Notes:

DRO = Diesel range organics

GRO = Gasoline range organics

B = Benzene

T = Toluene

E = Ethylbenzene

X = Total xylenes

MTBE = Methyl tert-butyl ether

TBA = Tert-butyl alcohol

DIPE = Di-isopropyl ether

ETBE = Ethyl tert-butyl ether

TAME = Tert-amyl methyl ether

SPH = Separate phase hydrocarbons

TOC = Top of casing (surveyed)

Calc. GW Elev. = Calculated groundwater elevation = TOC - Depth to Water + 0.75*(Measured SPH Thickness); assuming a specific gravity of 0.75 for SPH

ft-MSL = feet above mean sea level

µg/L = Micrograms per liter

< = Analyte was not detected above the specified method detection limit (MDL); except after 2006 Quarter 2 where reporting limits are used.

- = Not measured or analyzed

J = Estimated value (less than the method reporting limit and greater than or equal to the method detection limit)

Refer to the reports in which data was first presented for more information on historical data.

DRO analyzed by EPA Method 8015 Modified.

GRO analyzed by EPA Method 8015 Modified. The carbon chain range used for analysis since 2000 Quarter 2 is C4-C12.

BTEX and oxygenates analyzed by EPA Method 8260B since 2000 Quarter 2.

DRY = Well dry during gauging or purging; not sampled

DUP = Duplicate sample

NS = Well not sampled

PO/CONTRACT: GEM-6-21909

Andrew Modugno
SECOR International Inc
290 Conejo Ridge Ave
Suite 200
Thousand Oaks, CA 91361

Dear Andrew Modugno,

This report contains the analytical results for the 13 samples received under chain of custody by STL Los Angeles on July 8, 2006. These samples are associated with your ARCO #1057 project.

STL Los Angeles certifies that the test results provided in this report meet all NELAP requirements for parameters for which accreditation is required or available. Any exceptions to NELAP requirements are noted in the case narrative. The case narrative is an integral part of the report. NELAP Certification Number for STL Los Angeles is 01118CA / E87652.

Any matrix related anomaly is footnoted within the report. A cooler receipt temperature between 2-6 degrees Celsius is within EPA acceptance criteria. The temperature(s) of the cooler received for this project can be found on the Project Receipt Checklist. Historical control limits for the LCS are used to define the estimate of uncertainty for a method. All applicable quality control procedures met method-specified acceptance criteria.

Preliminary results were sent via facsimile on Thursday, July 20, 2006.
This report shall not be reproduced except in full, without the written approval of the laboratory.

000037

This report contains [illegible] pages.

If you have any questions, please feel free to call me at (714) 258-8610.

Sincerely,

Beth Riley
Project Manager

CASE NARRATIVE

STL LOT NUMBER: **E6G100**138

The relative response factor (RRF) for Ethanol does not meet the GCLN criteria for either the initial calibration (ICAL) or the continuing calibration verification (CCV). Even though this criteria was not met, the RRF's for Ethanol were greater than 0.05; which, is consistent with the USEPA Contract Laboratory Program National Functional Guidelines for Organic Data Review and the data is suitable for use.

EDG 100:350

RE: Record Search for the Millennium Hollywood Towers Project

Dear Ms. Rosskam,

As per your request received on June 2, 2008, a records search was conducted for the above referenced project. The search includes a review of all recorded archaeological sites within a ½-mile radius of the project site as well as a review of cultural resource reports on file. In addition, the California Points of Historical Interest (PHI), the California Historical Landmarks (CHL), the California Register of Historical Resources (CR), the National Register of Historic Places (NR), the California State Historic Resources Inventory (HRI), and the City of Los Angeles Historic-Cultural Monuments (LAHCM) listings were reviewed for the above referenced project site. The following is a discussion of the findings.

Due to the sensitive nature of cultural resources, archaeological site locations are not released.

Hollywood, CA. USGS 7.5' Quadrangle

ARCHAEOLOGICAL RESOURCES:

One archaeological site (19-003543) has been identified within a ½-mile radius of the project site. It is not located within the project site. It is not listed on the Archaeological Determinations of Eligibility (DOE) list. No isolates have been identified within a ½-mile radius of the project site. No isolates are located within the project site.

HISTORIC RESOURCES:

Sixty-seven additional cultural resources (19-169074, 19-168085, 19-168086, 19-168087, 19-168088, 19-168089, 19-168090, 19-168091, 19-169092, 19-168093, 19-168094, 19-168095, 19-168096, 19-168097, 19-168098, 19-168099, 19-168100, 19-168101, 19-168102, 19-168103, 19-168104, 19-168105, 19-168106, 19-168107, 19-168108, 19-168109, 19-168110, 19-168111, 19-168112, 19-168113, 19-168114, 19-

168115, 19-168116, 19-168117, 19-168268, 19-168269, 19-168270, 19-168271, 19-168272, 19 168273, 19-168274, 19-168275, 19-168276, 19-168277, 19-168278, 19-168279. 19-168280, 19-168281, 19-168282, 19-168283, 19-168284, 19-168285, 19-168286, 19-168287, 19-168288, 19-168289, 19-168290, 19-168291, 19-168292, 19-168378. 19-168437, 19-168773, 19-168774, 19-168775, 19-168776, 19-169323, 19-174178*, and 19-187897) have been identified within the a ½-mile radius of the project site. One cultural resource is located within the project site.
(= Located within the project site)*

A review of the historic maps – Santa Monica (1902, and 1921) 15' USGS - indicated that in 1902, a network of improved roads and many structures were present. Two intermittent streams ran north of the project site. The Hollywood & Cahuenga Valley Railroad ran through the project radius. Place names included Hollywood and Colegrove. In 1921, there was marked increase in development of the area. All features mentioned above were still present.

The California Point of Historical Interest (2008) of the Office of Historic Preservation, Department of Parks and Recreation, lists no properties within a ½-mile radius of the project site.

The California Historical Landmarks (2008) of the Office of Historic Preservation, Department of Parks and Recreation, lists no properties within a ½-mile radius of the project site.

The California Register of Historical Resources lists 365 properties within a ½-mile radius of the project site (see enclosed HRI list for properties marked with a +). These are properties determined to have a National Register of Historic Places Status of 1 or 2, a California Historical Landmark numbering 770 and higher, or a Point of Historical Interest listed after 1/1/1998.

The National Register of Historic Places lists 222 properties within a ½-mile radius of the project site (see enclosed HRI list for properties marked with an *).

The City of Los Angeles Historic-Cultural Monuments lists 50 properties within a ½-mile radius of the project site (see below).

No. 165 Fire Station No. 27
When built in 1930, it was considered the largest fire station west of the Mississippi (27,00 square feet); designed by Peter K. Schabarum.
Located at 1355 North Cahuenga Blvd. Declared: 10/20/76.
19-169280

No. 180 (Site of) The filming of the first talking feature film
Currently KTLA-TV, this is the site of the filming, in October, 1927, of "The Jazz Singer," the first feature film with synchronized dialogue.
Located at 5800 Sunset Blvd. Declared: 9/21/77.
5858: 19 169360

No. 193 Pantages Theatre
An exceptional example of Art Deco architecture of the 1920's and 1930's, it was designed in 1929 by architect B. Marcus Priteca and interior decorator Anthony Heinsbergen. Opened on June 4, 1930 as the last and

:argest of a chain of theaters operated by vaudeville magnate Alexander Pantages, its interior is considered by many to be the most magnificent example of theater architecture in Los Angeles. Located at 6233 Hollywood Boulevard. Declared: 7/5/78.
19-167073

No. 194 Hollywood Walk of Fame
Conceived by the Hollywood Chamber of Commerce in the late 1950's the "walk" is a tribute to the artists who have made significant contributions to the film, radio, television and recording industries. It contains over 2,500 bronze stars embedded in charcoal terrazzo squares, each with its distinctive emblem identifying the category in which the recipient is being honored. Located on Hollywood Boulevard between Gower Street and Sycamore Avenue and on Vine Street between Yucca Street and Sunset Boulevard. Declared: 7/5/78.
19-167544

No. 227 Janes House
Designed by Oliver Dennis and Lyman Farwell, the Queen Anne-style house was built in 1902 and purchased by the Janes family in 1903. The Janes sisters, Carrie, Mabel, and Grace, for many years operated the Misses Janes Kindergarten in their home. The school was attended by children of the Hollywood community including those of Cecil B. DeMille and Charles Chaplin. Located at 6541 Hollywood Boulevard, Hollywood. Declared: 4/3/80.
19-167559

No. 315 Villa Carlotta
Designed by architect Arthur E. Harvey, the four-story brick structure was constructed in 1926. The structure is designed in Spanish Churrigueresque style. Incorporated in the construction is an elaborate system of sound-proofing, a system of water filtration, a central refrigeration system and a ventilation system which changes air in each apartment every five minutes. Located at 5959 Franklin Avenue. Declared: 10/28/86.
19-169316

No. 316 William Stromberg Clock
The William Stromberg Clock, a landmark on Hollywood Boulevard since 1927, is a boulevard street clock. It is associated with of the street's oldest retailers. Located at 6439 Hollywood Boulevard. Declared: 1/7/87.
19-167555

No. 329 Chateau Elysee
The Chateau Elysee was built as a residential hotel in 1928 by Mrs. Eleanor Ince. Arthur E. Harvey designed the building in the Chateau Revival architectural style. Located at 5930 Franklin Avenue. Declared: 9/23/87.
19-169315

No. 334 Security Trust & Savings Building
One of the first high-rise (seven stories) buildings on Hollywood Boulevard, it was designed by the architectural firm of Parkinson & Parkinson in 1921 in the beaux Art and Italian Renaissance Revival styles. Located at 6381-6385 Hollywood Boulevard. Declared: 12/18/87.
6381: 19-171016

No. 448 Whitley Court
This court, designed by Dennis & Farwell, consists of a grouping of four Dutch Colonial Revival duplexes, built in 1919, along each side of a central garden, with a Craftsman house, circa 1903, in the rear. This court's two-story bungalow style is now unique in the Hollywood area. Located at 1720-1728 Whitley Avenue. Declared: 12/13/88.

The California Historic Resources Inventory lists 752 properties that have been evaluated for historical significance within a ½-mile radius of the project site (see enclosed HRI properties list).

PREVIOUS CULTURAL RESOURCES INVESTIGATIONS:

Fifteen studies (LA447, LA1578, LA3496, LA3510, LA3682, LA4345, LA4580, LA4909, LA5095, LA5332, LA5348, LA6811, LA7992, LA8020, and LA8251) have been conducted within a ½-mile radius of the project site. Of these, none are located within the project site. There are 32 additional investigations located on the Hollywood, CA. 7.5' USGS Quadrangle that are potentially within a ½-mile radius of the project site. The reports are not mapped due to insufficient locational information.

RECOMMENDATIONS

Based on the results of the records search, cultural resources at the project site (the Capitol Records Tower is on the California Register) and in the area of potential effect may be affected by this project. While current surface conditions do not appear to allow for an adequate survey of potential surface or sub-surface cultural artifacts, a Phase I survey that also includes additional archival research could be useful in

determining the history of the project site and the likelihood of encountering cultural resources during project activities. Therefore, a Phase-I survey is recommended for the project, prior to the approval of project plans. It is also recommended that any historic properties (45 years and older) in the area of potential effect be identified, recorded, and evaluated for local, state, or national significance prior to the approval of project plans. It is also recommended that the Native American Heritage Commission should be consulted to identify if any additional traditional cultural properties or other sacred sites are known to be in the area.

The professional consultant you retain may request the records search map, archaeological site records, and bibliography from the Information Center referencing the SCCIC number listed above for a fee (per the fee schedule). Any resulting reports by the qualified consultant should be submitted to the South Central Coastal Information Center as soon as possible.

If you have any questions regarding the results presented herein, please contact the office at 714.278.5395 Monday through Thursday 9:00 am to 3:30 pm.

Should you require any additional information for the above referenced project, reference the SCCIC number listed above when making inquiries. Requests made after initial invoicing will result in the preparation of a separate invoice.

Sincerely,
SCCIC

Michelle Galaz
Staff Researcher

AR0073425

California Historical Resource Status Codes

1 Properties listed in the National Register (NR) or the California Register (CR)

1D Contributor to a district or multiple resource property listed in NR by the Keeper. Listed in the CR.
1S Individual property listed in NR by the Keeper. Listed in the CR.

1CL Listed in the CR as a contributor to a district or multiple resource property by the SHRC.
1CS Listed in the CR as individual property by the SHRC.
1CT Automatically listed in the California Register – Includes State Historical Landmarks 770 and above and Points of Historical Interest nominated after December 1997 and recommended for listing by the SHRC.

2 Properties determined eligible for listing in the National Register (NR) or the California Register (CR)

2B Determined eligible for NR as an individual property and as a contributor to an eligible district in a federal regulatory process. Listed in the CR.
2D Contributor to a district determined eligible for NR by the Keeper. Listed in the CR
2D2 Contributor to a district determined eligible for NR by consensus through Section 106 process. Listed in the CR.
2D3 Contributor to a district determined eligible for NR by Part I Tax Certification. Listed in the CR.
2D4 Contributor to a district determined eligible for NR pursuant to Section 106 without review by SHPO. Listed in the CR.
2S Individual property determined eligible for NR by the Keeper. Listed in the CR.
2S2 Individual property determined eligible for NR by a consensus through Section 106 process. Listed in the CR.
2S3 Individual property determined eligible for NR by Part I Tax Certification. Listed in the CR.
2S4 Individual property determined eligible for NR pursuant to Section 106 without review by SHPO. Listed in the CR.

2CB Determined eligible for CR as an individual property and as a contributor to an eligible district by the SHRC.
2CD Contributor to a district determined eligible for listing in the CR by the SHRC.
2CS Individual property determined eligible for listing in the CR by the SHRC.

3 Appears eligible for National Register (NR) or California Register (CR) through Survey Evaluation

3B Appears eligible for NR both individually and as a contributor to a NR eligible district through survey evaluation.
3D Appears eligible for NR as a contributor to a NR eligible district through survey evaluation.
3S Appears eligible for NR as an individual property through survey evaluation.

3CB Appears eligible for CR both individually and as a contributor to a CR eligible district through a survey evaluation.
3CD Appears eligible for CR as a contributor to a CR eligible district through a survey evaluation.
3CS Appears eligible for CR as an individual property through survey evaluation.

4 Appears eligible for National Register (NR) or California Register (CR) through other evaluation

4CM Master List - State Owned Properties – PRC §5024.

5 Properties Recognized as Historically Significant by Local Government

5D1 Contributor to a district that is listed or designated locally.
5D2 Contributor to a district that is eligible for local listing or designation.
5D3 Appears to be a contributor to a district that appears eligible for local listing or designation through survey evaluation.

5S1 Individual property that is listed or designated locally.
5S2 Individual property that is eligible for local listing or designation.
5S3 Appears to be individually eligible for local listing or designation through survey evaluation.

5B Locally significant both individually (listed, eligible, or appears eligible) and as a contributor to a district that is locally listed, designated, determined eligible or appears eligible through survey evaluation.

6 Not Eligible for Listing or Designation as specified

6C Determined ineligible for or removed from California Register by SHRC.
6L Landmarks or Points of Interest found ineligible for designation by SHRC.
6L Determined ineligible for local listing or designation through local government review process; may warrant special consideration in local planning.
6T Determined ineligible for NR through Part I Tax Certification process.
6U Determined ineligible for NR pursuant to Section 106 without review by SHPO.
6W Removed from NR by the Keeper.
6X Determined ineligible for the NR by SHRC or Keeper.
6Y Determined ineligible for NR by consensus through Section 106 process – Not evaluated for CR or Local Listing.
6Z Found ineligible for NR, CR or Local designation through survey evaluation.

7 Not Evaluated for National Register (NR) or California Register (CR) or Needs Revaluation

7J Received by OHP for evaluation or action but not yet evaluated
7K Resubmitted to OHP for action but not reviewed
7L State Historical Landmarks 1-769 and Points of Historical Interest designated prior to January 1998 – Needs to be reevaluated using current standards
7M Submitted to OHP but not evaluated – referred to NPS
7N Needs to be reevaluated (formerly NP Status Code 4)
7N1 Needs to be reevaluated (formerly NP 5C4) – may become eligible for NR w/restoration or when meets other specific conditions
7R Identified in Reconnaissance Level Survey: Not evaluated.
7W Submitted to OHP for action - withdrawn

THE NATIONAL ACADEMIES

Advisers to the Nation on Science, Engineering, and Medicine

The **National Academy of Sciences** is a private, nonprofit, self-perpetuating society of distinguished scholars engaged in scientific and engineering research, dedicated to the furtherance of science and technology and to their use for the general welfare. Upon the authority of the charter granted to it by the Congress in 1863, the Academy has a mandate that requires it to advise the federal government on scientific and technical matters. Dr. Ralph J. Cicerone is president of the National Academy of Sciences.

The **National Academy of Engineering** was established in 1964, under the charter of the National Academy of Sciences, as a parallel organization of outstanding engineers. It is autonomous in its administration and in the selection of its members, sharing with the National Academy of Sciences the responsibility for advising the federal government. The National Academy of Engineering also sponsors engineering programs aimed at meeting national needs, encourages education and research, and recognizes the superior achievements of engineers. Dr. Charles M. Vest is president of the National Academy of Engineering.

The **Institute of Medicine** was established in 1970 by the National Academy of Sciences to secure the services of eminent members of appropriate professions in the examination of policy matters pertaining to the health of the public. The Institute acts under the responsibility given to the National Academy of Sciences by its congressional charter to be an adviser to the federal government and, on its own initiative, to identify issues of medical care, research, and education. Dr. Harvey V. Fineberg is president of the Institute of Medicine.

The **National Research Council** was organized by the National Academy of Sciences in 1916 to associate the broad community of science and technology with the Academy's purposes of furthering knowledge and advising the federal government. Functioning in accordance with general policies determined by the Academy, the Council has become the principal operating agency of both the National Academy of Sciences and the National Academy of Engineering in providing services to the government, the public, and the scientific and engineering communities. The Council is administered jointly by both the Academies and the Institute of Medicine. Dr. Ralph J. Cicerone and Dr. Charles M. Vest are chair and vice chair, respectively, of the National Research Council.

The **Transportation Research Board** is one of six major divisions of the National Research Council. The mission of the Transportation Research Board is to provide leadership in transportation innovation and progress through research and information exchange, conducted within a setting that is objective, interdisciplinary, and multimodal. The Board's varied activities annually engage about 7,000 engineers, scientists, and other transportation researchers and practitioners from the public and private sectors and academia, all of whom contribute their expertise in the public interest. The program is supported by state transportation departments, federal agencies including the component administrations of the U.S. Department of Transportation, and other organizations and individuals interested in the development of transportation. **www.TRB.org**

AR0073429

VOLUME 2
UNINTERRUPTED FLOW

OVERVIEW

Volume 2 of the *Highway Capacity Manual* (HCM) contains six chapters that present analysis methods for uninterrupted-flow roadways—that is, roadways that have no fixed causes of delay or interruption external to the traffic stream. This volume addresses three types of uninterrupted-flow roadways:

- *Freeways*, defined as separated highways with full control of access and two or more lanes in each direction dedicated to the exclusive use of traffic;
- *Multilane highways*, defined as highways that do not have full control of access and that have two or more lanes in each direction, with traffic signals or roundabouts spaced at least 2 mi apart on average; and
- *Two-lane highways*, defined as roadways with one lane for traffic in each direction (except for occasional passing lanes or truck climbing lanes), with traffic signals, roundabouts, or stop-controlled intersections spaced at least 2 mi apart on average.

The HCM treats roadways that have traffic signals, roundabouts, or stop-controlled intersections spaced less than 2 mi apart on average as urban streets. Urban streets are discussed in Volume 3, Interrupted Flow.

VOLUME ORGANIZATION

Freeways

Traffic enters and exits a freeway via ramps. **Chapter 13, Freeway Merge and Diverge Segments,** focuses on locations where two or more traffic streams combine to form a single traffic stream (a *merge*) or where a single traffic stream divides to form two or more separate traffic streams (a *diverge*). These locations are most commonly ramp–freeway junctions but include points where mainline roadways join or separate. Chapter 13 can also be applied in an approximate way to ramp–highway junctions on multilane highways and collector–distributor roads. Ramp–street junctions are analyzed with the methods in the intersection and interchange chapters in Volume 3.

Sometimes freeway merges are closely followed by freeway diverges, or a one-lane off-ramp closely follows a one-lane on-ramp and the two are connected by a continuous auxiliary lane. In these cases, the traffic streams found from the ramps must cross each other over a significant length of freeway without the aid of traffic control devices (except for guide signs). The term "closely" implies that the distance between the merge and diverge segments is not sufficient for them to operate independently. Data on what is a short, **Chapter 12, Freeway Weaving Segments,** provides procedures for analyzing weaving operations on freeways.

VOLUME 2: UNINTERRUPTED FLOW
10. Freeway Facilities
11. Basic Freeway Segments
12. Freeway Weaving Segments
13. Freeway Merge and Diverge Segments
14. Multilane Highways
15. Two-Lane Highways

AR0073431

It can be applied in an approximate way to weaves on multilane highways and collector–distributor roads, but not to weaves on arterial streets.

The remaining portions of the freeway mainline that are not merge, diverge, or weaving segments (except for toll plazas, drawbridges, or similar points where freeway traffic may be temporarily required to stop) are covered in **Chapter 11, Basic Freeway Segments.** This chapter also provides information on the base conditions and passenger car equivalents for heavy vehicles that are common to all of the freeway chapters.

Chapter 10, Freeway Facilities, provides a methodology for analyzing extended lengths of freeway composed of continuously connected basic freeway, weaving, merge, and diverge segments. Such extended lengths are referred to as a *freeway facility*. In this terminology, the term *facility* does not refer to an entire freeway from beginning to end; instead, it refers to a specific set of connected segments that have been identified for analysis. In addition, the term does not refer to a freeway system consisting of several interconnected freeways.

The methodologies of Chapters 11, 12, and 13 all focus on a single time period of interest, generally the peak 15 min within a peak hour. However, Chapter 10's methodology allows for the analysis of multiple and continuous 15 min periods and is capable of identifying breakdowns and the impact of such breakdowns over space and time.

Multilane Highways

Chapter 14, Multilane Highways, presents analysis methods for the portions of multilane highways away from the influence of signalized intersections or other forms of intersection traffic control that interrupt the flow of traffic on the highway. Many multilane highways will have periodic signalized intersections, even if the average signal spacing is well over 2 mi. In such cases, the multilane highway segments that are more than 2 mi away from any signalized intersections are analyzed with the Chapter 14 methodology. Isolated signalized intersections should be analyzed with the methodology of Chapter 18, Signalized Intersections.

Bicycles are typically permitted on multilane highways, and multilane highways often serve as primary routes for both commuter cyclists (on suburban highways) and recreational cyclists (on rural highways). Chapter 14 presents a method for estimating the bicycle level of service (LOS) on multilane highways.

Two-Lane Highways

Chapter 15, Two-Lane Highways, presents analysis methods for the portions of two-lane highways that are away from the influence of intersection traffic control that interrupts the flow of traffic. In general, any segment that is 2.0 to 3.0 mi from the nearest signalized intersection, roundabout, or intersection where the highway is STOP controlled would fit into this category. Where these interruptions in traffic are less than 2.0 mi apart, the facility should be classified as an urban street and analyzed with the methodologies of Chapter 16, Urban Street Facilities, and Chapter 17, Urban Street Segments, which are located in Volume 3.

AR0073432

Chapter 15 can be used to analyze three classes of two-lane highways:

- *Class I* highways are ones where motorists expect to travel at relatively high speeds, such as major intercity routes, primary connectors of major traffic generators, daily commuter routes, or major links in state or national highway networks;
- *Class II* highways are ones where motorists do not necessarily expect to travel at high speeds, such as highways serving as access routes to Class I facilities, serving as scenic or recreational routes, or passing through rugged terrain; and
- *Class III* highways are ones serving moderately developed areas, such as portions of a Class I or Class II highway passing through small towns or developed recreational areas or longer segments passing through more spread-out recreational areas, with increased roadside densities.

Two-lane highways often serve as routes for recreational cyclists. Chapter 15 presents a method for estimating the bicycle LOS on these highways.

RELATED CHAPTERS

Volume 1

The chapters in Volume 2 assume that the reader is already familiar with the concepts presented in the Volume 1 chapters, in particular the following:

- *Chapter 2, Applications*—types of HCM analysis, types of roadway system elements, and traffic flow characteristics;
- *Chapter 3, Modal Characteristics*—evaluation of demand, peak and analysis hours, K and D factors, facility types by mode, and interactions between modes;
- *Chapter 4, Traffic Flow and Capacity Concepts*—traffic flow parameters and factors that influence capacity; and
- *Chapter 5, Quality and Level-of-Service Concepts*—performance measures, service measures, and LOS.

Volume 3

The intersection and interchange chapters (Chapters 18–22) are used to determine the operations of freeway ramp–street junctions and the operations of isolated traffic signals, roundabouts, and STOP-controlled intersections along multilane and two-lane highways. In the context of Volume 2, it is particularly important to examine the length of the queue extending back from a freeway off-ramp–street junction, since long queues may affect freeway operations, a situation that is not accounted for in the HCM techniques.

AR0073433

VOLUME 4: APPLICATIONS GUIDE
Methodological Details
- 25: Freeway Facilities: Supplemental
- 26: Freeway and Highway Segments: Supplemental
- 27: Freeway Weaving: Supplemental
- 28: Freeway Ramps and Diverges: Supplemental
- 35: Active Traffic Management

Case Studies
Technical Reference Library

Volume 4

Five chapters in Volume 4 (accessible at www.HCM2010.org) provide additional information that supplements the material presented in Volume 2. These chapters are as follows:

- *Chapter 25, Freeway Facilities: Supplemental*—details of the computations used in the Chapter 10 methodology, and computational engine flowcharts and linkage lists.
- *Chapter 26, Freeway and Highway Segments: Supplemental*—examples of applying alternative tools to situations that are not addressed by the Chapter 11 method for basic freeway segments, and state-specific default values for heavy-vehicle percentage that apply to all Volume 2 chapters.
- *Chapter 27, Freeway Weaving: Supplemental*—examples of applying alternative tools to situations not addressed by the Chapter 12 method.
- *Chapter 28, Freeway Ramps and Diverges: Supplemental*—examples of applying alternative tools to situations not addressed by the Chapter 13 method, and
- *Chapter 35, Active Traffic Management*—descriptions of active traffic management strategies, a discussion of the mechanisms by which they affect demand, capacity, and performance, and general guidance on possible evaluation methods for active traffic management techniques.

Access Volume 4 at www.HCM2010.org

The *HCM Applications Guide* in Volume 4 provides three case studies on the analysis of uninterrupted-flow facilities:

- *Case Study No. 3* illustrates the process of applying HCM techniques to the analysis of a two-lane highway.
- *Case Study No. 4* illustrates the process of applying HCM techniques to the analysis of a freeway; and
- *Case Study No. 5* illustrates the application of alternative tools to a freeway facility in a situation where HCM techniques are unsuitable.

Case Studies No. 3 and No. 4 focus on the process of applying the HCM rather than on the details of performing calculations (which are addressed by the example problems in the Volume 2 chapters). These case studies' computational results were developed by using HCM2000 methodologies and therefore may not match the results obtained from applying the HCM 2010. However, the process of application is the focus, not the specific computational results.

The Technical Reference Library in Volume 4 contains copies of (or links to) many of the documents referenced in Volume 2 and its supplemental chapters. Because the Chapter 10 methodology is too complex to be implemented by manual pencil-and-paper techniques, the FRETEVAL-2010 spreadsheet has been developed to implement the methodology's calculations. The Technical Reference Library contains a copy of the spreadsheet along with a user's guide.

AR0073434

LEVELS OF ANALYSIS AND ANALYSIS TOOLS

As discussed in Chapter 2, Applications, HCM methodologies can be applied to the operations, design, preliminary engineering, and planning levels of analysis. These levels differ both in the amount of field data used in the analysis (as opposed to default values) and in the way the HCM is applied (iteratively, to find a design that meets a desired set of criteria, or as a single application, to evaluate performance given a particular set of inputs). Each Volume 2 chapter provides a section that discusses how to apply the chapter to these different levels of analysis, along with a section with recommended default values for planning and preliminary engineering analyses.

Three Volume 2 chapters (10, 14, and 15) provide generalized service volume tables applicable to freeway facilities, multilane highways, and two-lane highways, respectively. These tables can be used for large-scale planning efforts when the goal is to analyze a large number of facilities to determine where problems might exist or arise or where improvements might be needed. Any facilities identified as likely to experience problems or need improvement should then be subjected to a more detailed analysis that takes into account the existing or likely future characteristics of the specific facility before any detailed decisions on implementing specific improvements are made. Because the service volumes provided in these tables are highly dependent on the default values assumed as inputs, it is recommended that users wishing to apply generalized service volume tables develop their own tables by using local default values, in accordance with the processes described in Appendix A and Appendix B of Chapter 6, HCM and Alternative Analysis Tools.

Chapter 6 also describes in general terms the conditions under which the use of alternative tools to supplement HCM capacity and quality-of-service procedures should be considered. Each Volume 2 chapter contains a section discussing the potential application of alternative tools to the specific system element addressed by the chapter, and Chapters 26–28 in Volume 4 provide example problems illustrating applications of alternative tools to address HCM limitations. Each chapter lists the specific limitations of its methodology. The major limitations are summarized as follows:

- Freeways
  - Operations of oversaturated freeway segments (but not necessarily oversaturated freeway facilities, as discussed later),
  - Multiple overlapping breakdowns or bottlenecks,
  - Conditions where off-ramp queues extend back onto the freeway or affect the operation of exiting vehicles,
  - Operation of separated high-occupancy vehicle (HOV) facilities and weaving movements between HOV and general-purpose lanes,
  - Toll plaza operations, and
  - Ramp-metering effects.

AR0073435

- *Multilane highways*
  - Operations during oversaturated conditions
  - The impacts of shoulder parking activity, bus stops, or significant pedestrian activity
  - Possible queuing impacts when a multilane highway segment transitions to a two-lane highway segment
  - Differences between various types of median barriers, and the difference between the impact of a median barrier and a two-way left-turn lane

  The range of values used to develop the bicycle LOS model. Although the model has been successfully applied to rural multilane highways, users should be aware that conditions on many of these highways are outside the range of values used to develop the model.
- *Two-lane highways*
  - Operations during oversaturated conditions
  - Impact of intersection traffic control on the overall facility LOS
  - The range of values used to develop the bicycle LOS model. Although the model has been successfully applied to rural two-lane highways, users should be aware that conditions on many of these highways are outside the range of values used to develop the model.

If an analysis of an individual freeway segment reveals the segment to be oversaturated, then Chapter 10, Freeway Facilities, must be used to assess operation of the segment and its impacts on upstream and downstream sections. If the Chapter 10 analysis reveals that the oversaturation would extend beyond the geographic or temporal boundaries of the analysis, then the boundaries of the Chapter 10 analysis should be expanded to contain the oversaturation. If expanding the boundaries of the analysis is not practical, then no analytical tool, including the HCM, can give a complete answer in this situation.

1. INTRODUCTION

VOLUME 2: UNINTERRUPTED FLOW
10. Freeway Facilities
11. Basic Freeway Segments
12. Freeway Weaving Segments
13. Freeway Merge and Diverge Segments
14. Multilane Highways
15. Two-Lane Highways

A freeway is a separated highway with full control of access and two or more lanes in each direction dedicated to the exclusive use of traffic. Freeways are composed of various uniform segments that may be analyzed to determine capacity and level of service (LOS). Three types of segments are found on freeways.

- *Freeway merge and diverge segments*: Segments in which two or more traffic streams combine to form a single traffic stream (merge) or a single traffic stream divides to form two or more separate traffic streams (diverge).
- *Freeway weaving segments*: Segments in which two or more traffic streams traveling in the same general direction cross paths along a significant length of freeway without the aid of traffic control devices (except for guide signs). Weaving segments are formed when a diverge segment closely follows a merge segment or when a one-lane on-ramp closely follows a one-lane on-ramp and the two are connected by a continuous auxiliary lane.
- *Basic freeway segments*: All segments that are not merge, diverge, or weaving segments.

Analysis methodologies are detailed for basic freeway segments in Chapter 11, for weaving segments in Chapter 12, and for merge and diverge segments in Chapter 13.

Chapter 10, Freeway Facilities, provides a methodology for analyzing extended lengths of freeway composed of continuously connected basic freeway, weaving, merge, and diverge segments. Such extended lengths are referred to as *a freeway facility*. In this terminology, the term *facility* does not refer to an entire freeway from beginning to end; instead, it refers to a specific set of connected segments that have been identified for analysis. In addition, the term does not refer to a freeway system consisting of several interconnected freeways.

The methodologies of Chapters 11, 12, and 13 focus on a single time period of interest, generally the peak 15 min within a peak hour. This chapter's methodology allows for the analysis of multiple and continuous 15-min time periods and is capable of identifying breakdowns and the impact of such breakdowns over space and time.

The methodology is integral with the FREEVAL-2010 model, which implements the complex computations involved. This chapter discusses the basic principles of the methodology and its application. Chapter 25, Freeway Facilities Supplemental, provides a complete and detailed description of all the algorithms that define the methodology. The Technical Reference Library in Volume 4 contains a user's guide to FREEVAL-2010 and an executable spreadsheet that implements the methodology.

AR0073441

SEGMENTS AND INFLUENCE AREAS

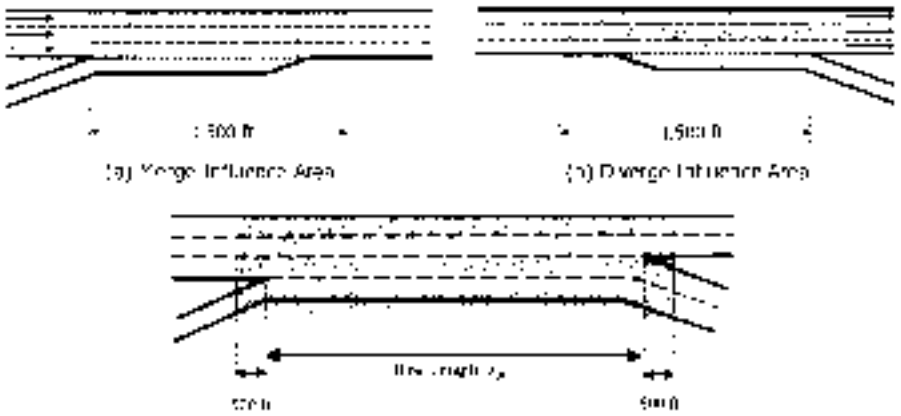
It is important that the definition of freeway segments and their influence areas be clearly understood. The influence areas of merge, diverge, and weaving segments are as follows:

- *Weaving segment*: The base length of the weaving segment plus 500 ft upstream of the entry point to the weaving segment and 500 ft downstream of the exit point from the weaving segment; entry and exit points are defined as the points where the appropriate edges of the merging and diverging lanes meet.
- *Merge segment*: From the point where the edges of the travel lanes of the merging roadways meet to a point 1,500 ft downstream of that point.
- *Diverge segment*: From the point where the edges of the travel lanes of the merging roadways meet to a point 1,500 ft upstream of that point.

Points where the "edges of travel lanes" meet are most often defined by pavement markings.

The influence areas of merge, diverge, and weaving segments are illustrated in Exhibit 10-1.

Exhibit 10-1
Influence Areas of Merge, Diverge, and Weaving Segments



Basic freeway segments are any other segments along the freeway that are not within those defined influence areas, which is not to say that basic freeway segments are not affected by the presence of adjacent and nearby merge, diverge, and weaving segments. Particularly when a segment breaks down, its effects will propagate to both upstream and downstream segments, regardless of type. Furthermore, the general impact of the frequency of merge, diverge, and weaving segments on the general operation of all segments is taken into account by the free-flow speed of the facility.

Basic freeway segments, therefore, do exist even on urban freeways where merge and diverge points (most often ramps) are closely spaced. Exhibit 10-2 illustrates this point. It shows a 9,100 ft (1.7 mi) length of freeway with four ramp terminals, two of which form a weaving segment. Even with an average ramp spacing of less than 0.5 mi, this length of freeway contains three basic freeway segments. The lengths of these segments are relatively short, but, in terms of

AR0073442

analysis methodologies, they must be treated as basic freeway segments. Thus, while it is true that many urban freeways will be dominated by frequent merge, diverge, and weaving segments, there will still be segments classified and analyzed as basic freeway segments.

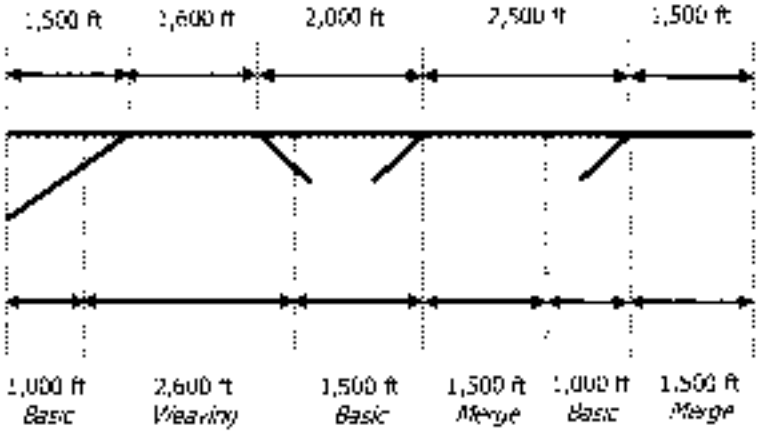


Exhibit 10-2
Basic Freeway Segments on an Urban Freeway

FREE-FLOW SPEED

Free-flow speed is strictly defined as the theoretical speed when the density and flow rate on the study segment are both zero. Chapter 11, Basic Freeway Segments, presents speed–flow curves that indicate that the free-flow speed on freeways is expected to prevail at flow rates between 0 and 1,000 passenger cars per hour per lane (pc/h/ln). In this broad range of flows, speed is insensitive to flow rates. This characteristic simplifies and allows for measurement of free-flow speeds in the field.

Chapter 11 also presents a methodology for estimating the free-flow speed of a basic freeway segment if it cannot be directly measured. The free-flow speed of a basic freeway segment is sensitive to three variables:

- Lane widths,
- Lateral clearances, and
- Total ramp density.

The most critical of these variables is total ramp density. *Total ramp density* is defined as the average number of on-ramp, off-ramp, major merge, and major diverge junctions per mile. It applies to a 6-mi segment of freeway facility, 3 mi upstream and 3 mi downstream of the midpoint of the study segment.

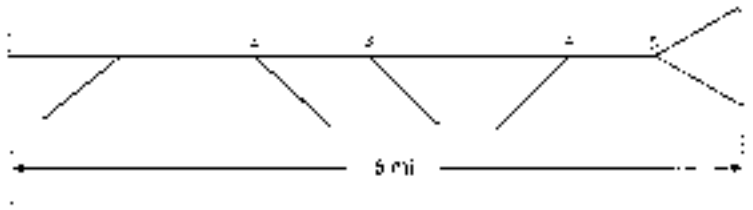
While the methodology for determining free-flow speed is provided in Chapter 11, Basic Freeway Segments, it is also applied in Chapter 12, Freeway Weaving Segments, and Chapter 13, Freeway Merge and Diverge Segments. Thus, free-flow speed affects the operation of all basic, weaving, merge, and diverge segments on a freeway facility.

The free-flow speed is an important characteristic, as the capacity, service flow rates (*SF*), service volumes (*SV*), and daily service volumes (*DSV*) all depend on it.

AR0073443

Exhibit 10-3 illustrates the determination of total ramp density on a 6-mi length of freeway facility.

Exhibit 10-3
Ramp Density Determination



As illustrated in Exhibit 10-3, there are four ramp terminals and one major diverge point in the 6-mi segment illustrated. The total ramp density is, therefore, 5/6 = 0.83 ramps/mi.

CAPACITY OF FREEWAY FACILITIES

Capacity traditionally has been defined for segments of uniform roadway, traffic, and control conditions. When facilities consisting of a series of connected segments are considered, the concept of capacity is more complicated.

The methodologies of Chapters 11, 12, and 13 allow the capacity of each basic freeway, freeway weaving, freeway merge, and freeway diverge segment to be estimated. It is highly unlikely that every segment of a facility will have the same roadway, traffic, and control conditions and even less likely that they will have the same capacity.

Conceptual Approach to the Capacity of a Freeway Facility

Consider the example shown in Exhibit 10-4. It illustrates five consecutive segments that are to be analyzed as one "freeway facility." Demand flow rates v_i, capacities c_i, and actual flow rates v_i are shown, as are the resulting v_i/c_i and v_i/c_i ratios. A lane is added in Segment 3 (even though this segment begins with an off-ramp), providing higher capacities for Segments 3, 4, and 5 than in Segments 1 and 2. The example analyzes three scenarios.

In Scenario 1, none of the demand flow rates exceeds the capacities of the segments that make up the facility. Thus, no breakdowns occur, and the actual flow rates are the same as the demand flow rates ($v_i = v_i$ for this scenario). None of the v_i/c_i or v_i/c_i ratios exceeds 1.00, although the highest ratios (0.979) occur in Segment 5.

Scenario 2 adds 200 vehicles per hour (veh/h) of demand to each segment (essentially another 200 veh/h of through freeway vehicles). In this case, Segment 5 will experience a breakdown—that is, the demand flow rate will exceed the capacity. In this segment, demand flow rate v_i differs from the actual flow rate v_i, as the actual flow rate v_i can never exceed the capacity c_i.

In Scenario 3, all demand flow rates are increased by 10%, which, in effect, keeps the relative values of the segment demand flow rates constant. In this case, demand flow rate will exceed capacity in Segments 1 and 5. Again, the demand flow rates and actual flow rates will differ in these segments.

AR0073444

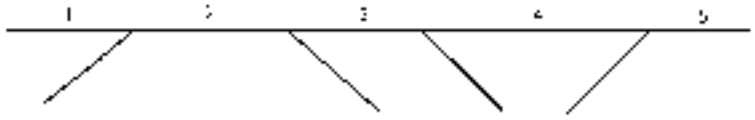


Exhibit 10-4
Example of the Effect of Segment Capacity on a Freeway Facility

Scenario	Performance Measures	Freeway Segment 1	2	3	4	5
Scenario 1 (stable flow)	Demand v_i, veh/h	3,400	3,500	3,400	4,200	4,400
	Capacity c_i, veh/h	4,000	4,000	4,500	4,500	4,500
	Volume v_i, veh/h	3,400	3,500	3,400	4,200	4,400
	v_i/c_i ratio	0.850	0.875	0.756	0.933	0.978
	v_i/c_i ratio	0.850	0.875	0.756	0.933	0.978
Scenario 2 (add 200 veh/h to each segment)	Demand v_i, veh/h	3,600	3,700	3,600	4,400	4,600
	Capacity c_i, veh/h	4,000	4,000	4,500	4,500	4,500
	Volume v_i, veh/h	3,600	3,700	3,600	4,400	4,500
	v_i/c_i ratio	0.900	0.925	0.800	0.978	1.022
	v_i/c_i ratio	0.900	0.925	0.800	0.978	1.000
Scenario 3 (increase demand by 10% in all segments)	Demand v_i, veh/h	3,740	3,850	3,740	4,840	5,060
	Capacity c_i, veh/h	4,000	4,000	4,500	4,500	4,500
	Volume v_i, veh/h	3,740	3,850	3,740	4,500	4,500
	v_i/c_i ratio	0.935	0.963	0.831	1.078	1.120
	v_i/c_i ratio	0.935	0.963	0.831	1.000	1.000

Note: Shaded cells indicate segments where demand exceeds capacity.

This example highlights a number of points that make the analysis of freeway facilities very complicated:

1. It is critical to the methodology that the difference between demand flow rate v_i and actual flow rate v_i be highlighted and that both values be clearly and appropriately labeled.
2. In Scenarios 2 and 3, the analysis of Exhibit 10-4 is inadequate and misleading. In Scenario 2, when Segment 5 breaks down, queues begin to form and to propagate upstream. Thus, even though the demands in Segments 1 through 4 are less than the capacity of those segments, the queues generated by Segment 5 over time will propagate through Segments 1 through 4 and significantly affect their operation. In Scenario 3, Segments 4 and 5 fail, and queues are generated, which also propagate upstream over time.
3. It might be argued that the analysis of Scenario 1 is sufficient to understand the facility operation as long as all segments are undersaturated (i.e., all segment v/c ratios are less than or equal to 1.00). However, when any segment v_i/c_i ratio exceeds 1.00, such a simple analysis ignores the spreading impact of breakdowns in space and time.
4. In Scenarios 2 and 3, the segments downstream of Segment 5 will also be affected, as demand flow is prevented from reaching those segments by the Segment 5 (and Segment 4 in Scenario 3) breakdowns and queues.
5. In this example, it is also important to note that the segment(s) that break down first do not have the lowest capacities. Segments 1 and 2, with lower capacities, do not break down in any of the scenarios. Breakdown occurs first in Segment 5, which has one of the higher capacities.

Considering all these complications, the capacity of a freeway facility is defined as follows:

AR0073445

Freeway facility capacity is the capacity of the critical segment among those segments composing the freeway facility. This capacity must, for analysis purposes, be compared with the demand flow rate on the critical segment.

The critical segment is defined as the segment that will break down first, given that all traffic, roadway, and control conditions do not change, including the spatial distribution of demands on each component segment. This definition is not a simple one. It depends on the relative demand characteristics and can change over time as the demand pattern changes. Facility capacity may be more than the capacity of the component segment with the lowest capacity. Therefore, it is important that individual segment demands and capacities be evaluated. The fact that one of these segments will be the critical one and will define the facility capacity does not diminish the importance of the capacities of other segments in the defined facility.

Base Capacity of Freeway Facilities

In the methodologies of Chapters 11, 12, and 13, a base capacity is used. The base capacity represents the capacity of the facility, assuming that there are no heavy vehicles in the traffic stream and that all drivers are regular users of the segment. The base capacity for all freeway segments varies with the free-flow speed, as indicated in Exhibit 10-5.

Exhibit 10-5
Free-Flow Speed vs. Base Capacity for Freeways

Free-Flow Speed (mi/h)	Base Capacity (pc/h/ln)
75	2,400
70	2,400
65	2,350
60	2,300
55	2,250

The equation given in Chapter 11, Basic Freeway Segments, for estimating the free-flow speed of a segment is as shown in Equation 10-1:

Equation 10-1

$$FFS = 75.4 - f_{LW} - f_{LC} - 3.22\,TRD^{0.84}$$

where

FFS = free-flow speed (mi/h),

f_{LW} = adjustment for lane width (mi/h),

f_{LC} = adjustment for lateral clearance (mi/h), and

TRD = total ramp density (ramps/mi).

The process for determining the value of adjustment factors is described in Chapter 11.

Because the base capacity of a freeway segment is directly related to the free-flow speed, it is possible to construct a relationship between base capacity and the lane width, lateral clearance, and total ramp density of the segment. If the lane width and lateral clearance are taken to be their base values (12 and 6 ft, respectively), a relationship between base capacity and total ramp density emerges, as shown in Exhibit 10-6.

AR0073446

Base capacity is expressed as a flow rate for a 15-min analysis period, not a full-hour volume. It also represents a flow rate in pcph, with no heavy vehicles, and a driver population familiar with the characteristics of the analysis segment.

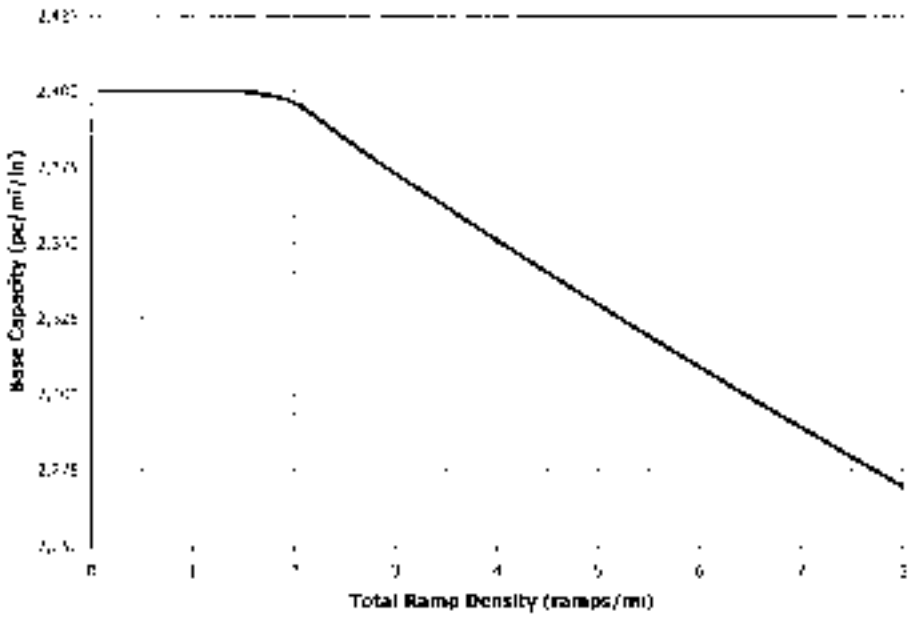

Exhibit 10-6
Base Capacity vs. Total Ramp Density

Segment Capacity vs. Facility Capacity

Free-flow speed is a characteristic of a length of freeway extending 3 mi upstream and 3 mi downstream of the center point of an analysis segment. The segment may be a basic freeway segment, a weaving segment, a merge segment, or a diverge segment. In essence, it is a measure of the impact of overall facility characteristics on the operation of the individual analysis segment centered in the defined 6-mi length.

This concept can be somewhat generalized where freeway facility analysis is involved. If conditions (particularly ramp density) are similar along a greater length of freeway, it is acceptable to compute the total ramp density for the greater length and apply it to all segments within the analysis length. This process assumes that moving the "center" of a 6-mi length for each component segment will not result in a significant change in the free-flow speed.

The capacity of a nearly homogeneous freeway facility is, for all practical purposes, the same as the capacity of a basic freeway segment with the same roadway and traffic characteristics. Consider the following:

- Merge and diverge segments have the same capacity as a similar basic freeway segment. As discussed in Chapter 11, the presence of merge and diverge segments on a freeway may affect operating characteristics, generally reducing speeds and increasing densities, but does not reduce capacity.
- Weaving segments often have per lane capacities that are less than those of the entering and leaving basic freeway segments. In almost all cases, however, weaving segments have more lanes than the entering and

AR0073447

leaving basic freeway segments. Thus, the impact on the capacity of the mainline freeway most often is negligible.

This does not mean, however, that the capacity at each component segment of a facility is the same. Each segment has its own demand and demand characteristics. Demand flow rate can change at every entry and exit point along the freeway, and the percent of heavy vehicles can change too. Terrain also can change at various points along the freeway.

Changes in heavy vehicle presence can change the capacity of individual segments within a defined facility. Changes in the split of movements in a weaving segment can change its capacity. In the same way, changes in the relative demand flows at on- and off-ramps can change the location of the critical segment within a defined facility and its capacity.

As noted previously, the capacity of a freeway facility is defined as the capacity of its critical segment.

LOS: COMPONENT SEGMENTS AND THE FREEWAY FACILITY

LOS of Component Segments

Chapters 11, 12, and 13 provide methodologies to determine the LOS in basic, weaving, merge, and diverge segments. In all cases, LOS F is identified when v/c is greater than 1.00. Such breakdowns are easily identified, and users are referred to this chapter.

This chapter's methodology provides an analysis of breakdown conditions, including the spatial and time impacts of a breakdown. Thus, in the performance of a facility level analysis, LOS F in a component segment can be identified (a) when the segment v/c is greater than 1.00 and (b) when a queue from a downstream breakdown extends into an upstream segment. The latter cannot be done by using the individual segment analysis procedures of Chapters 11, 12, and 13.

Thus, when facility-level analysis is undertaken by using the methodology of this chapter, LOS F for a component segment will be identified in two different ways.

- When v/c is greater than 1.00, or
- When the density is greater than 45 pc/mi/ln for basic freeway segments or 43 pc/mi/ln for weaving, merge, or diverge segments.

The latter identifies segments in which queues have formed as a result of downstream breakdowns.

LOS for a Freeway Facility

Because LOS for basic, weaving, merge, and diverge segments on a freeway is defined in terms of density, LOS for a freeway facility is also defined on the basis of density.

A facility analysis will result in a density determination and LOS for each component segment. The facility LOS will be based on the weighted average density for all segments within the defined facility. Weighting is done on the

AR0073448

basis of segment length and the number of lanes in each segment, as shown in Equation 10-2:

$$D_R = \frac{\sum_{i=1}^{n} D_i \times L_i \times N_i}{\sum_{i=1}^{n} L_i \times N_i}$$

Equation 10-2

where

D_R = average density for the facility (pc/mi/ln),

D_i = density for segment i (pc/mi/ln),

L_i = length of segment i (ft),

N_i = number of lanes in segment i, and

n = number of segments in the defined facility.

The LOS criteria for a freeway facility are shown in Exhibit 10-7. They are the same criteria used for basic freeway segments.

Exhibit 10-7
LOS Criteria for Freeway Facilities

Level of Service	Density (pc/mi/ln)
A	≤10
B	>10–18
C	>18–26
D	>26–35
E	>35–45
F	>45 or
	any component v/c ratio > 1.00

Use of a LOS descriptor for the overall freeway facility must be done with care. It is critical that the LOS for individual segments composing the facility also be reported. Because the overall LOS is an average, it may mask serious problems in individual segments of the facility.

This is particularly important if one or more of the component segments are operating at LOS F. As described in this chapter's methodology section, the freeway facility methodology applies models to estimate the propagation of the effects of a breakdown in time and space. When breakdowns exist in one or more segments of a facility, the average LOS is of limited use. The average LOS applies to a specific time period, usually 15 min.

While LOS A through D are defined by using the same densities that apply to basic freeway segments, LOS F for a facility is defined as a case in which any component segment of the freeway exceeds a v/c ratio of 1.00 or the average density over the defined facility exceeds 45 pc/mi/ln. In such a case, this chapter's methodology allows the analyst to map the impacts of this breakdown in time and space, and close attention to the individual LOS of component segments is necessary.

AR0073449

SERVICE FLOW RATES, SERVICE VOLUMES, AND DAILY SERVICE VOLUMES FOR A FREEWAY FACILITY

Just as each segment of a freeway facility has its own capacity, each segment also has a set of service flow rates SF_i for each LOS. A service flow rate is the maximum directional rate of flow that can be sustained in a given segment without violating the criteria for LOS *i*. Service flow rates are stated in vehicles per hour under prevailing roadway, traffic, and control conditions. By definition, the service flow rate for LOS E is synonymous with capacity for all uninterrupted-flow facilities and their component segments.

Chapters 11, 12, and 13 provide complete discussions of how to determine service flow rates for basic, weaving, merge, and diverge freeway segments.

A service volume SV_i is the maximum hourly directional volume that can be sustained in a given segment without violating the criteria for LOS *i* during the worst 15 min of the hour (period with the highest density) under prevailing roadway, traffic, and control conditions. Once a set of service flow rates has been established for a segment, the service volume is found from Equation 10-3:

Equation 10-3

$$SV_i = SF_i \times PHF$$

where

SV_i = service volume for LOS *i* (veh/h),

SF_i = service flow rate for LOS *i* (veh/h), and

PHF = peak hour factor.

A daily service volume DSV_i is the maximum total daily volume in both directions that can be sustained in a given segment without violating the criteria for LOS *i* in the peak direction in the worst 15 min of the peak hour under prevailing roadway, traffic, and control conditions. Given a set of service volumes for a segment, the daily service volume is found from Equation 10-4:

Equation 10-4

$$DSV_i = \frac{SV_i}{K \times D}$$

where

DSV_i = daily service volume (veh/day),

K = proportion of daily traffic occurring in the peak hour of the day, and

D = proportion of traffic in the peak direction during the peak hour of the day.

The capacity of a freeway facility has been defined as the capacity under prevailing conditions of the critical segment. For consistency, therefore, other service flow rates must also be applied to the critical segment.

For an overall understanding of the freeway facility, the LOS and service flow rates (or service volumes or daily service volumes) of the individual component segments must be considered along with the overall average LOS for the defined facility and its service flow rate.

AR0073450

GENERALIZED DAILY SERVICE VOLUMES FOR FREEWAY FACILITIES

Generalized daily service volume tables provide a means to assess all freeways in a region or jurisdiction quickly to determine which segments need to be assessed more carefully using operational analysis to ameliorate existing or pending problems.

To generate a generalized daily service volume table for freeway facilities, several simplifying assumptions must be made. The assumptions made here include the following:

1. All segments of the freeway have the same basic number of lanes (two, three, or four in each direction).
2. Lane widths are 12 ft, and lateral clearances are 6 ft.
3. All on-ramps and off-ramps handle the same percentage of freeway traffic. This setup maintains a reasonably consistent demand flow rate on each segment of the facility.
4. The first ramp on the defined freeway facility is an off-ramp. This assumption is necessary to implement Item 3, below.
5. Given the demand characteristics of Items 2 and 3, all daily service volumes are stated in terms of the demand entering the defined freeway facility at its upstream boundary.
6. The terrain is the same in all segments of the facility.
7. The heavy vehicle percentage is the same in all segments of the facility.

On the basis of these assumptions, generalized daily service volume tables are shown in Exhibit 10-8 (for urban freeways) and Exhibit 10-9 (for rural freeways).

Generalized service volumes are provided for level and rolling terrain; for four lane, six lane, and eight lane freeways (both directions); and for a variety of combinations of the K factor and D-factor. To use the table, analysts must select a combination of K and D appropriate for their state or region. Additional assumptions made for urban and rural freeways are listed here.

Assumptions for urban freeways:

- Total ramp density = 3.00 ramps/mi (i.e., ½-mi average spacing between ramps);
- 5 % trucks, no recreational vehicles (RVs), and no buses;
- PHF = 0.95; and
- $f_p = 1.00$

Assumptions for rural freeways:

- Total ramp density = 0.20 ramp/mi (i.e., 5-mi average spacing between ramps);
- 12 % trucks, no RVs, and no buses;
- PHF = 0.88; and
- $f_p = 0.85$

AR0073451

Generalized daily service volumes are based on the maximum service flow rate values for basic freeway segments. Exhibit 10-7 (Chapter 11) shows maximum service flow rates MSF_i for basic freeway segments. They are converted to service flow rates under prevailing conditions by multiplying by the number of lanes in one direction N, the heavy-vehicle adjustment factor f_{HV}, and the driver-population adjustment factor f_p. Equation 10-3 and Equation 10-4 are then used to convert the service flow rate SF_i to a service volume SV_i and a daily service volume DSV_i.

By combining these equations, the daily service volumes DSV_i of Exhibit 10-8 and Exhibit 10-9 are estimated from Equation 10-5:

Equation 10-5

$$DSV_i = \frac{MSF_i \times N \times f_{HV} \times f_p \times PHF}{K \times D}$$

where all variables are as previously defined.

In applying Equation 10-5, the values of MSF_i are selected from Exhibit 10-17 (Chapter 11), and values for the heavy-vehicle and driver-population adjustment factors are computed in accordance with the methodology of Chapter 11. The MSF_i for LOS E, which is capacity, may be taken directly from Exhibit 10-5, based on the total ramp density, as lane widths and lateral clearances are standard and have no effect on the DSV_i and thus no effect on the resulting capacities.

Exhibit 10-8 and Exhibit 10-9 are provided for general planning use and should not be used to analyze any specific freeway or to make final decisions on important design features. A full operational analysis using this chapter's methodology is required for such specific applications.

The exhibits are useful, however, in evaluating the overall performance of many freeways within a jurisdiction, as a first pass in determining where problems might exist or arise, and in deciding where improvements might be needed. Any freeways identified as likely to experience problems or to need improvement, however, should be subjected to a full operational analysis before any detailed decisions on implementing specific improvements are made.

Daily service volumes are heavily affected by the K and D factors chosen as typical for the analysis. It is important that the analyst use values that are reasonable for the facilities under study. Also, if any characteristic differs significantly from the typical values used to develop Exhibit 10-8 and Exhibit 10-9, the values taken from these exhibits will not be representative of the study facilities.

Note: Assumptions include the following: 12ft lanes, 6ft sides, 0.92 PHF, 0.2 trucks, $f_G = 0.97$, 12-ft lanes, and 5-0 lanes. Operation values do not represent specific segments of service.

ACTIVE TRAFFIC MANAGEMENT AND OTHER MEASURES TO IMPROVE PERFORMANCE

Active traffic management (ATM) consists of the dynamic and continuous monitoring and control of traffic operations on a facility to improve its performance. Examples of ATM measures include congestion pricing, ramp metering, changeable message signs, incident response programs, and speed harmonization (variable speed limits).

ATM measures can influence both the nature of demand for the facility and the ability of the facility to deliver the capacity tailored to serve the demand. ATM measures can improve facility performance, sometimes significantly.

Other advanced design and management measures, not specifically included in the definition of ATM, can also significantly improve facility performance. These measures include auxiliary lanes, narrow lanes, high occupancy vehicle (HOV) lanes, temporary use of shoulders, and designated truck lanes and ramps.

This methodology does not reflect all these measures. However, ramp metering can be taken into account by altering on-ramp demands in accordance

AR0073454

with metering rates. Auxiliary lanes and narrow lanes are taken into account in the segment methodologies for basic freeway segments and weaving segments.

Other measures are not accounted for in this methodology. Chapter 35 provides a more detailed discussion of ATM and other advanced design and management strategies and insight into how their impacts may be evaluated

AR0073455

2. METHODOLOGY

The methodology presented in this chapter provides for the integrated analysis of a freeway facility composed of contiguous segments. The methodology builds on the models and procedures for individual segments, as described in Chapter 11, Basic Freeway Segments, Chapter 12, Freeway Weaving Segments, and Chapter 13, Freeway Merge and Diverge Segments.

SCOPE OF THE METHODOLOGY

Because the freeway facility methodology builds on the segment methodologies of Chapters 11, 12, and 13, it incorporates all aspects of those chapters' methodologies. This methodology adds the ability to consider a number of linked segments over a number of time periods and to determine some overall operational parameters that allow for the assessment of a facility LOS and capacity.

This methodology also adds the ability to analyze operations when LOS F exists on one or more segments of the defined facility. In Chapters 11, 12, and 13, the existence of a breakdown (LOS F) is identified for a given segment, as appropriate. The segment methodologies do not, however, provide tools for analyzing the impacts of such breakdowns over time and space.

The methodology analyzes a set of connected segments over a set of sequential 15-min periods. In deciding which segments and time periods to analyze, two principles should be observed.

1. The first and last segments of the defined facility should not operate at LOS F.
2. The first and last time periods of the analysis should not include any segments that operate at LOS F.

When the first segment operates at LOS F, there is a queue extending upstream that is not included in the facility definition and that therefore cannot be analyzed. When the last segment operates at LOS F, there may be a downstream bottleneck outside the facility definition. Again, the impacts of this congestion cannot be evaluated when it is not fully contained within the defined facility. LOS F in either the first or last time period creates similar problems with regard to time. If the first time period is at LOS F, then LOS F may exist in previous time periods as well. If the last time period is at LOS F, subsequent periods may be at LOS F as well. The impacts of a breakdown cannot be fully analyzed unless it is fully contained within the defined facility and defined total analysis period. The same problems would exist if the analysis were conducted by using simulation.

There is no limit to the number of time periods that can be analyzed. The length of the freeway should be less than the distance a vehicle traveling at the average speed can achieve in 15 min. This specification generally results in a maximum facility length between 9 and 12 mi.

This methodology is based on research sponsored by the Federal Highway Administration (1).

AR0073456

LIMITATIONS OF THE METHODOLOGY

The methodology has the following limitations:

1. The methodology does not account for the delays caused by vehicles using alternative routes or vehicles leaving before or after the analysis period.
2. Multiple overlapping breakdowns or bottlenecks are difficult to analyze and cannot be fully evaluated by this methodology. Other tools may be more appropriate for specific applications beyond the capabilities of the methodology. Consult Chapter 6, HCM and Alternative Analysis Tools, for a discussion of simulation and other models.
3. Spatial, temporal, modal, and total demand responses to traffic management strategies are not automatically incorporated into the methodology. On viewing the facility traffic performance results, the analyst can modify the demand input manually to analyze the effect of user-demand responses and traffic growth. The accuracy of the results depends on the accuracy of the estimation of user-demand responses.
4. The methodology can address local oversaturated flow but cannot directly address systemwide oversaturation flow conditions.
5. The completeness of the analysis will be limited if freeway segments in the first time interval, the last time interval, and the first freeway segment (in all time periods) have demand to capacity ratios greater than 1.00. The rationale for these limitations is discussed in the section on demand-to-capacity ratio.
6. The existence of HOV lanes on freeways raises the issues of the operating characteristics of such lanes and their effect on operating characteristics on the remainder of the freeway. The methodology does not directly address separated HOV facilities and does not account for the interactions between HOV lanes and mixed-flow lanes and the weaving that may be produced.
7. The method does not address conditions in which off-ramp capacity limitations result in queues that extend onto the freeway or affect the behavior of off-ramp vehicles.
8. The method does not address toll plaza operations or their effect on freeway facility operations.

Given enough time, the analyst can analyze a completely undersaturated time–space domain manually, although it is very difficult and time consuming. It is not expected that analysts will ever manually analyze a time–space domain that includes oversaturation. FREEVAL-2010 is a computational engine that can be used to implement the methodology, regardless of whether the time–space domain contains oversaturated segments and time periods. It is available in the Technical Reference Library section of Volume 4 of the *Highway Capacity Manual* (HCM).

AR0073457

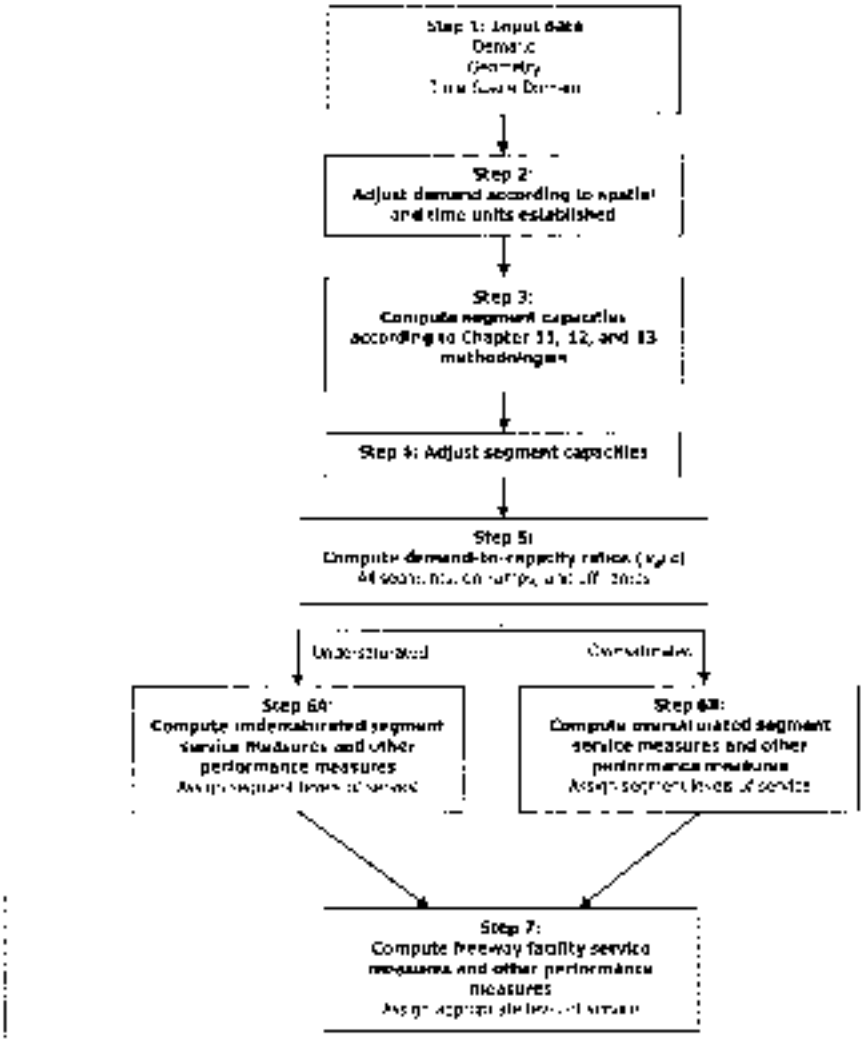
Because this chapter's methodology incorporates the methodologies for basic, weaving, merging, and diverging freeway segments, the limitations of those procedures also apply here.

The method does not include analysis of the street-side terminals of freeway on- and off-ramps. The methodologies of Chapters 18, 19, 20, and 21 should be used for intersections that are signalized, two-way STOP-controlled, all-way STOP-controlled, and roundabouts, respectively. Chapter 22, Interchange Ramp Terminals, provides a more comprehensive analysis of freeway interchanges where the street-side ramp terminals are signalized intersections or roundabouts.

OVERVIEW

Exhibit 10-10 summarizes the methodology for analyzing freeway facilities. The methodology adjusts vehicle speeds appropriately to account for the effects in adjacent segments. The methodology can analyze freeway traffic management strategies only in cases for which 15-min intervals are appropriate and for which reliable data for estimated capacity and demand exist.

Exhibit 10-10
Freeway Facility Methodology



AR0073458

COMPUTATIONAL STEPS

The purpose of this section is to describe the methodology's computational modules. To simplify the presentation, the focus is on the functions of, and rationale for, each module. Chapter 25 presents an expanded version of this section, including all the supporting analytical models and equations.

Step 1: Input Data

Data concerning demand, geometry, and the time–space domain must be specified. As the methodology builds on segment analyses, all data for each segment and each time period must be provided, as indicated in Chapter 11 for basic freeway segments, Chapter 12 for weaving segments, and Chapter 13 for merge and diverge segments.

Demand

Demand flow rates must be specified for each segment and time period. Because analysis of multiple time periods is based on consecutive 15-min periods, the demand flow rates for each period must be provided. This condition is in addition to the requirements for isolated segment analyses.

Demand flow rates must be specified for the entering freeway mainline flow and for each on ramp and off-ramp within the defined facility. The following information is needed for each time period to determine the demand flow rate:

- Demand flow rate (veh/h),
- Percent trucks (%),
- Percent RVs (%), and
- Driver population factor (f_p).

For weaving segments, demand flow rates must be identified by component movement: freeway to freeway, ramp to freeway, freeway to ramp, and ramp to ramp. Where this level of detail is not available, the following procedure may be used to estimate the component flows. It is not recommended, however, as weaving segment performance is sensitive to the split of demand flows.

- *Ramp–ramp segments:* Assume that the ramp-to-ramp flow is 0. The ramp-to-freeway flow is then equal to the on ramp flow, the freeway-to-ramp flow is then equal to the off-ramp flow.
- *Major–major segments:* On-ramp flow is apportioned to the two exit legs (freeway and ramp) in the same proportion as the total flow on the exit legs (freeway and ramp).

The driver population factor is normally 1.00, unless the driver population is dominated by unfamiliar users, in which case a value between 0.85 and 1.00 is assigned, on the basis of local characteristics and knowledge.

AR0073459

Geometry

All geometric features for each segment of the facility must be specified, including the following:

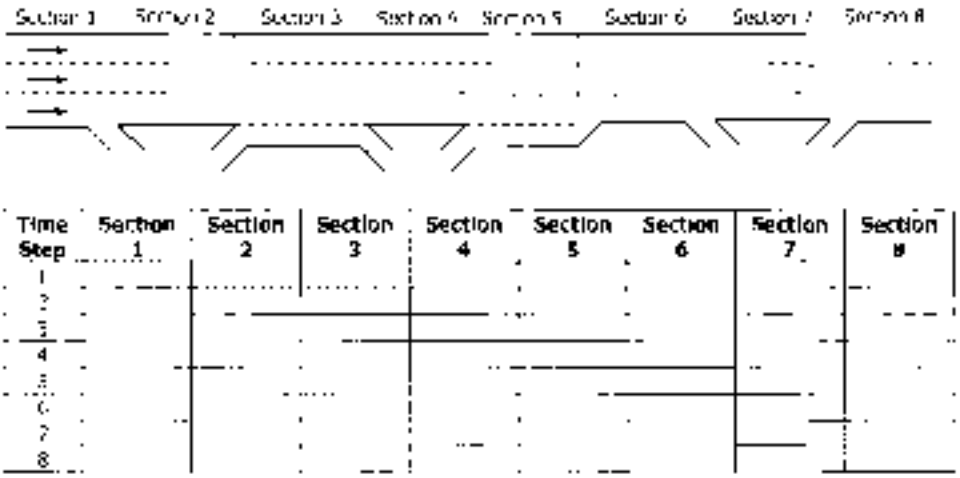
- Number of lanes;
- Average lane width;
- Right-side lateral clearance;
- Terrain;
- Free-flow speed; and
- Location of merge, diverge, and weaving segments, with all internal geometry specified, including the number of lanes on ramps and at ramp–freeway junctions or within weaving segments, lane widths, existence and length of acceleration or deceleration lanes, distances between merge and diverge points, and the details of lane configuration where relevant.

Geometry does not change by time period, so this information is given only once, regardless of the number of time periods under study.

Time–Space Domain

A time–space domain for the analysis may be established. The domain consists of a specification of the freeway sections included in the defined facility and an identification of the time intervals for which the analysis is to be conducted. A typical time–space domain is shown in Exhibit 10-11.

Exhibit 10-11
Example Time–Space Domain for Freeway Facility Analysis



The horizontal scale indicates the distance along the freeway facility. A freeway section boundary occurs where there is a change in demand—that is, at each on-ramp or off-ramp or where a lane is added or dropped. These areas are referred to as *sections*, but many adjustments will be made within the procedure to determine where *section* boundaries should be for analysis. This process relies on the influence areas of merge, diverge, and weaving segments, discussed earlier in this chapter, and on variable length limitations specified in Chapter 12 for weaving segments and in Chapter 13 for merge and diverge segments.

AR0073460

The vertical scale indicates the study time duration. Time extends down the time–space domain, and the scale is divided into 15-min intervals. In the example shown, there are 8 sections and 8 time steps, yielding $8 \times 8 = 64$ time–space cells, each of which will be analyzed within the methodology.

The boundary conditions of the time–space domain are extremely important. The time–space domain will be analyzed as an independent freeway facility having no interaction with upstream or downstream portions of the freeway or any connecting facilities, including other freeways and surface facilities. Therefore, no congestion should occur along the four boundaries of the time–space domain. The cells located along the four boundaries should all have demands less than capacity and should contain undersaturated flow conditions. A proper analysis of congestion within the time–space domain can occur only if the congestion is limited to internal cells not along the time–space boundaries.

Converting the Horizontal Scale from Sections to Analysis Segments

The sections of the defined freeway facility are established by using points where demand changes or where lanes are added or subtracted. This, however, does not fully describe individual segments for analysis within the methodology. The conversion from sections to analysis segments can be done manually by applying the principles discussed here.

Chapter 13, Freeway Merge and Diverge Segments, indicates that each merge segment extends from the merge point to a point 1,500 ft downstream of it. Each diverge segment extends from the diverge point to a point 1,500 ft upstream of it. This allows for a number of scenarios affecting the definition of analysis segments within the defined freeway.

Consider the illustration of Exhibit 10-12. It shows a one-lane on-ramp followed by a one-lane off-ramp with no auxiliary lane between them. The illustration assumes that there are no upstream or downstream ramps or weaving segments that impinge on this section.

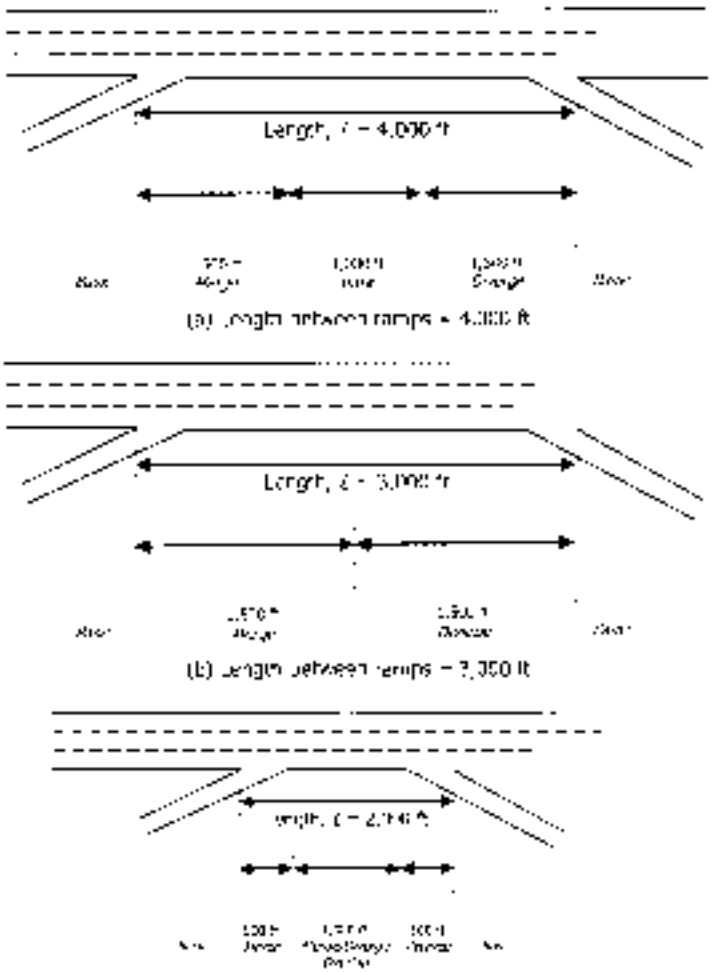
In Exhibit 10-12(a), there are 4,000 ft between the two ramps. Therefore, the merge segment extends 1,500 ft downstream, and the diverge segment extends 1,500 ft upstream, which leaves a 1,000-ft basic freeway segment between them.

In Exhibit 10-12(b), there are 3,000 ft between the two ramps. The two 1,500-ft ramp influence areas define the entire length. Therefore, there is no basic freeway segment between the merge and diverge segments.

In Exhibit 10-12(c), the situation is more complicated. With only 2,000 ft between the ramps, the merge and diverge influence areas overlap for a distance of 1,000 ft.

AR0073461

Exhibit 10-12
Defining Analysis Segments for a Ramp Configuration

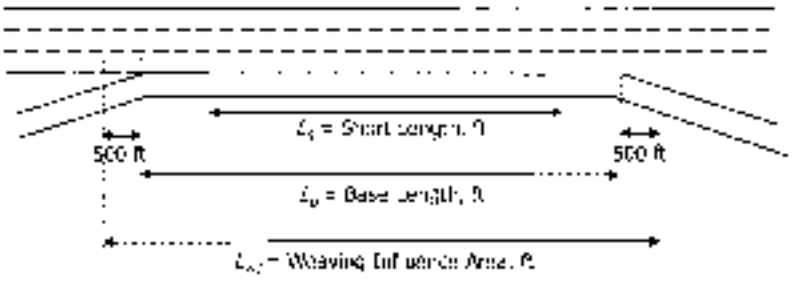


Chapter 13, Freeway Merge and Diverge Segments, covers this situation where ramp influence areas overlap. The analysis is conducted for each ramp separately. The analysis producing the worst LOS (or service measure value if the LOS is equivalent) is used to define operations in the overlap area.

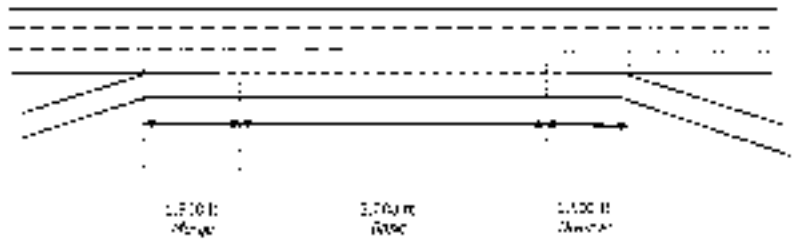
The facility methodology goes through the logic of distances and segment definitions to convert section boundaries to segment boundaries for analysis. If the distance between an on-ramp and off-ramp is less than the full influence area of 1,500 ft, the worst case is applied to the distance between the ramps, while basic segment criteria are applied to segments upstream of the on-ramp and downstream of the off-ramp.

A similar situation can arise where weaving configurations exist. Exhibit 10-13 illustrates a weaving configuration within a defined freeway facility. In this case, the distance between the merge and diverge ends of the configuration must be compared with the maximum length of a weaving segment, L_{max}. If the distance between the merge and diverge points is less than or equal to L_{max}, then the entire segment is analyzed as a weaving segment, as shown in Exhibit 10-13(a).

AR0073462



(a) Case I: $L_B \leq L_{W(1)}$ (weaving segment exists)



(b) Case II: $L_B > L_{W(1)}$ (isolated merge and diverge exists)

Exhibit 10-13
Defining Analysis Segments for a Weaving Configuration

Three lengths are involved in analyzing a weaving segment:

- The base length of the segment, measured from the points where the edges of the travel lanes of the merging and diverging roadways converge (L_B);
- The influence area of the weaving segment (L_W), which includes 500 ft upstream and downstream of L_B; and
- The short length of the segment, defined as the distance over which lane changing is not prohibited or discouraged by markings (L_S).

The latter is the length that is used in all the prediction models for weaving segment analysis. The results of these models, however, apply to a distance of L_S + 500 ft upstream and L_S + 500 ft downstream. For further discussion of the various lengths applied to weaving segments, consult Chapter 12.

If the distance between the merge and diverge points is greater than $L_{W(1)}$, then the merge and diverge segments are too far apart to form a weaving segment. As shown in Exhibit 10-13(b), the merge and diverge segments are treated separately, and any distance remaining between the merge and diverge influence areas is treated as a basic freeway segment.

In the Chapter 12 weaving methodology, the value of $L_{W(1)}$ depends on a number of factors, including the split of component flows, demand flows, and other traffic factors. A weaving configuration could therefore qualify as a weaving segment in some analysis periods and as separate merge, diverge, and possibly basic segments in others.

In segmenting the freeway facility for analysis, merge, diverge, and weaving segments are identified as illustrated in Exhibit 10-12 and Exhibit 10-13. All segments not qualifying as merge, diverge, or weaving segments are basic freeway segments.

AR0073463

However, a long basic freeway section may have to be divided into multiple segments. This situation occurs when there's a sharp break in terrain within the section. For example, a 5-mi section may have a constant demand and a constant number of lanes. If there is a 2-mi level terrain portion followed by a 4% grade that is 3 mi long, then the level terrain portion and the specific grade portion would be established as two separate, consecutive basic freeway segments.

Step 2: Adjust Demand According to Spatial and Time Units Established

Traffic counts taken at each entrance to and exit from the defined freeway facility (including the mainline entrance and mainline exit) for each time interval serve as inputs to the methodology. While entrance counts are considered to represent the current entrance demands for the freeway facility (provided that there is not a queue on the freeway entrance), the exit counts may not represent the current exit demands for the freeway facility because of congestion within the defined facility.

For planning applications, estimated traffic demands for each entrance to and exit from the freeway facility for each time interval serve as input to the methodology. The sum of the input demands must equal the sum of the output demands in every time interval.

Once the entrance and exit demands are calculated, the demands for each cell in every time interval can be estimated. The segment demands can be thought of as filtering across the time–space domain and filling each cell of the time–space matrix.

Demand estimation is needed if the methodology uses actual freeway counts. If demand flows are known or can be projected, they are used directly without modification.

The methodology includes a demand estimation model that converts the input set of freeway exit 15-min counts to a set of vehicle flows that desire to exit the freeway in a given 15-min period. This demand may not be the same as the 15-min exit count because of upstream congestion within the defined freeway facility.

The procedure sums the freeway entrance demands along the entire directional freeway facility, including the entering mainline segment, and compares this sum with the sum of freeway exit counts along the direct-to-final freeway facility, including the departing mainline segment. This procedure is repeated for each time interval. The ratio of the total facility entrance counts to total facility exit counts is called the *time interval scale factor* and should approach 1.00 when the freeway exit counts are, in fact, freeway exit demands.

Scale factors greater than 1.00 indicate increasing levels of congestion within the freeway facility, with exit counts underestimating the actual freeway exit demands. To provide an estimate of freeway exit demand, each freeway exit count is multiplied by the time interval scale factor.

Equation 10-6 and Equation 10-7 summarize this process.

AR0073464

$$f_{adj} = \frac{\sum V_{entry}}{\sum V_{exit}}$$

Equation 10-6

$$V_{adj,exit} = V_{exit} \times f_{adj}$$

Equation 10-7

where

f_{adj} = unit-interval scale factor for time period t,

V_{entry} = 15-min entering count for time period t and entering location j (veh),

V_{exit} = 15-min exit count for time period t and exiting location j (veh), and

$V_{adj,exit}$ = adjusted 15-min exit demand for time period t and exiting location j (veh).

Once the entrance and exit demands are determined, the traffic demands for each section and each time period can be calculated. On the time–space domain, section demands can be viewed as projecting horizontally across Exhibit 10-11, with each cell containing an estimate of its 15-min demand.

Because each time period is separately balanced, it is advisable to limit the total length of the defined facility to a distance that can be traversed within 15 min. In practical terms, this practice limits the length of the facility to 9 to 12 mi.

Step 3: Compute Segment Capacities According to Chapter 11, 12, and 13 Methodologies

Segment capacity estimates are determined by the methodologies of Chapter 11 for basic freeway segments, Chapter 12 for weaving segments, and Chapter 13 for merge and diverge segments. All estimates of segment capacity should be carefully reviewed and compared with local knowledge and available traffic information for the study site, particularly where known bottlenecks exist.

On-ramp and off-ramp roadway capacities are also determined in this step with the Chapter 13 methodology. On-ramp demands may exceed on-ramp capacities and limit the traffic demand entering the facility. Off-ramp demands may exceed off-ramp capacities and cause congestion on the freeway, although that impact is not accounted for in this methodology.

All capacity results are stated in vehicles per hour under prevailing roadway and traffic conditions.

The effect of a predetermined ramp-metering plan can be evaluated in this methodology by overriding the computed ramp roadway capacities. The capacity of each entrance ramp in each time interval is changed to reflect the specified ramp-metering rate. This feature not only allows for evaluating a prescribed ramp-metering plan but also permits the user to improve the ramp-metering plan through experimentation.

Freeway design improvements can be evaluated with this methodology by modifying the design features of any portion of the freeway facility. For example, the effects of adding auxiliary lanes at critical locations and full lanes over multiple segments can be assessed.

AR0073465

Step 4: Adjust Segment Capacities

Segment capacities can be affected by a number of conditions not normally accounted for in the segment methodologies of Chapters 11, 12, and 13. These values may include the effects of short-term and long-term lane closures for construction or major maintenance operations, the effects of adverse weather conditions, and the effects of other environmental factors.

At lane drops, permanent reductions in capacity occur. They are included in the base methodology, which automatically accounts for the capacity of segments on the basis of the number of lanes in the segment and other prevailing conditions.

Capacity Reductions due to Construction and Major Maintenance Operations

Capacity reductions due to construction activities can be divided into short-term work zone lane closures, typically for maintenance, and long-term lane closures, typically for construction. A primary distinction between short-term work zones and long-term construction zones is the nature of the barriers used to demarcate the work area. Long-term construction zones generally use portable concrete barriers, while short term work zones use standard channelizing devices (e.g., traffic cones, drums) in accordance with the *Manual on Uniform Traffic Control Devices for Streets and Highways* (2). Capacity reductions due to long-term construction or major maintenance operations generally last several weeks, months, or even years, depending on the nature of the work. Short-term closures generally last a few hours.

Short-Term Work Zones

Research (3) suggests that a capacity of 1,600 pc/h/ln be used for short-term freeway work zones, regardless of the lane-closure configuration. However, for some types of closures, a higher value could be appropriate.

This base value should be adjusted for other conditions, as follows:

1. *Intensity of work activity*: The intensity of work activity refers to the number of workers on the site, the number and size of work vehicles in use, and the proximity of the work activity to the travel lanes. Several types of work also contribute to intensity in terms of rubbernecking by drivers passing through the site. Research (3) suggests that the base value of 1,600 pc/h/ln be adjusted by as much as ±10% for work activity that is more or less intensive than normal. It does not, however, define what constitutes "normal" intensity, so this factor should be applied on the basis of professional judgment and local experience.
2. *Effects of heavy vehicles*: Because the base value is given in terms of pc/h/ln, it is recommended that the heavy vehicle adjustment factor (f_{HV}) be applied. A complete discussion of the heavy vehicle adjustment factor and its determination are included in Chapter 12, Basic Freeway Segments. Equation 12-5 shows how the factor is determined.

AR0073466

$$f_{HV} = \frac{1}{1 + P_T(E_T - 1) + P_R(E_R - 1)}$$ **Equation 10-8**

where

f_{HV} = heavy-vehicle adjustment factor,

P_T = proportion of trucks and buses in the traffic stream,

P_R = proportion of RVs in the traffic stream,

E_T = passenger-car equivalent for trucks and buses, and

E_R = passenger-car equivalent for RVs.

Passenger car equivalents for trucks and buses and for RVs may be found in Chapter 13, Basic Freeway Segments.

7. *Presence of ramps:* If there is an entrance ramp within the taper area approaching the lane closure or within 500 ft downstream of the beginning of the full lane closure, the ramp will have a noticeable effect on the capacity of the work zone for handling mainline traffic. This situation arises in two ways, (a) the ramp traffic generally forces its way in, so it directly reduces the amount of mainline traffic that can be handled, and (b) the added turbulence in the merge area may slightly reduce capacity (even though such turbulence does not reduce capacity on a normal freeway segment without lane closures). If at all possible, on-ramps should be located at least 1,500 ft upstream of the beginning of the full lane closure to maximize the total work zone throughput. If that cannot be done, then either the ramp volume should be added to the mainline volume to be served or the capacity of the work zone should be decreased by the ramp volume (up to a maximum of one-half of the capacity of one lane) on the assumption that, at very high volumes, mainline and ramp vehicles will alternate.

Equation 10-9 is used to estimate the resulting reduced capacity in vehicles per hour

$$c_a = \{[(1{,}600 - I) \times f_{HV}] \times N\} - R$$ **Equation 10-9**

where

c_a = adjusted mainline capacity (veh/h),

I = adjustment factor for type, intensity, and proximity of work activity, pc/h/ln (ranges between +150 pc/h/ln),

f_{HV} = heavy-vehicle adjustment factor,

N = number of lanes open through the work zone, and

R = manual adjustment for on-ramps (veh/h).

AR0073467

Long-Term Construction Zones

There have been many studies of long-term construction zone capacities. They are summarized in Exhibit 10-14.

Exhibit 10-14
Capacity of Long-Term Construction Zones (veh/h/ln)

State	Normal Lanes to Reduced Lanes						Source
	2 to 1	3 to 2	3 to 1	4 to 3	4 to 2	4 to 1

Source: Adapted from Dudek et al. (16).

It is easy to see from Exhibit 10-14 that capacities through long-term construction zones are highly variable and depend on many site-specific characteristics. Therefore, it is better to base this adjustment on local data and experience. If such data do not exist and cannot be reasonably acquired, the default values of Exhibit 10-14 may be used to provide an approximate estimate of construction zone capacity.

Lane-Width Consideration

The impact of lane width on general freeway operations is incorporated into the methodology of Chapter 11, Basic Freeway Segments, for determining free-flow speed. As free-flow speed affects capacity, it follows that restricted lane widths will negatively affect capacity.

As free-flow speeds are not estimated specifically for work or construction zones, it is appropriate to add an adjustment factor for the effect of lane widths narrower than 12 ft in a work or construction zone. The factor f_{ln} would be added to Equation 10-9, as shown in Equation 10-10:

Equation 10-10

$$c_w = c_i \times f_{ln}$$

where c_i is the adjusted capacity of the work or construction zone reflecting the impact of restricted lane width, in vehicles per hour, and all other variables are as previously defined.

The value of the adjustment factor f_{ln} is 1.01 for 12 ft lanes, 0.91 for lanes between 10.0 and 11.9 ft, and 0.85 for lanes between 9.0 and 9.9 ft. If lanes narrower than 9.0 ft are in use, local observations should be made to calibrate an appropriate adjustment.

AR0073468

Capacity Reductions due to Weather and Environmental Conditions

A number of studies have attempted to address the impacts of adverse weather and environmental conditions on the capacity of freeways. Comprehensive results on a range of conditions in Iowa, summarized in Exhibit 10-15, are provided elsewhere (74).

Type of Condition	Intensity of Condition	Percent Reduction in Capacity	
		Average	Range
Rain	>0 ≤ 0.10 in/h	2.01	1.17–3.43
	>0.10 < 0.25 in/h	7.24	5.67–10.10
	>0.25 in/h	14.13	10.72–17.67
Snow	>0 ≤ 0.05 in/h	4.29	3.44–5.51
	>0.05 ≤ 0.10 in/h	8.06	5.48–11.53
	>0.10 ≤ 0.50 in/h	11.04	7.45–13.75
	>0.50 in/h	22.43	19.53–27.62
Temperature	<0°F ≥ -4°F	1.07	1.06–1.08
	<4°F ≥ -4°F	1.50	1.48–1.52
	<-4°F	8.45	6.62–10.27
Wind	>10 ≤ 20 mi/h	1.07	0.74–1.41
	>20 mi/h	1.47	0.74–2.19
Visibility	<1 > 0.50 mi	9.67	One site
	<0.50 < 0.25 mi	11.07	One site
	<0.25 mi	10.49	One site

Source: Adapted from Agarwal et al. (74).

Exhibit 10-15
Capacity Reductions due to Weather and Environmental Conditions in Iowa

Additional information is available in the literature. Additional data and information on the impacts of rain on freeway capacity are provided elsewhere (75, 76), as are information on the effects of snow (76) and insights and information on the effects of fog (77, 78).

A study of capacity on German autobahns provides data on the differences between daytime and nighttime conditions on wet or dry pavements (79). Exhibit 10-16 summarizes these results.

Freeway Lanes	Weekday or Weekend	Daylight Dry	Dark Dry	Daylight Wet	Dark Wet
6	Weekday (% change*)	1,489	1,299 (-14%)	1,310 (-12%)	923 (-38%)
6	Weekend (% change*)	1,480	1,099 (-21%)	1,014 (-27%)	—
4	Weekday (% change*)	1,739	1,415 (-19%)	1,421 (-18%)	913 (-47%)
4	Weekend (% change*)	1,551	1,158 (-25%)	1,104 (-29%)	—

Note: *Percent change from daylight, dry conditions for the same day of week.
Source: Adapted from Brilon and Ponzlet (79).

Exhibit 10-16
Capacities on German Autobahns Under Various Conditions (veh/h/ln)

This exhibit is interesting in that the daylight, dry capacities of German autobahns are somewhat less than might be expected on U.S. freeways. This situation could be due to the higher speeds that prevail on the autobahns and heavy-vehicle presence, which are not reflected in these vehicle/h/ln statistics.

The daylight wet versus dry capacity reductions are greater in Exhibit 10-16 than those shown in Exhibit 10-15, which may again be a reflection of different driver behavior characteristics in Germany and the United States. Darkness alone has a significant impact on autobahn capacities. Since winter peak hours occur

AR0073469

when it is dark in many areas of the country, such reductions are important to incorporate.

The difference between weekday and weekend capacities is also interesting and is on the order of 7% to 10% in Exhibit 10-16. This impact is generally reflected in the use of a driver-population factor f_p (see Chapter 11). Weekend driving populations may not be as familiar with the facility as weekday commuters. Even familiar users may not drive as aggressively on weekend recreational or other trips when the pressure of a specific schedule may be less than is present during the week.

Capacity Reductions due to Traffic Accidents or Vehicular Breakdowns

Capacity reductions due to traffic accidents or other incidents are generally short-lived, ranging from less than 1 h before they can be cleared to as long as 2 h for an accident involving severe injuries, fatalities, hazardous materials cleanup, or cleanup of other materials from vehicles involved in accidents.

One study (*20*) reported the mean duration of a traffic incident to be 37 min, with more than half the incidents lasting 30 min or less and 82% lasting less than 1 h.

Exhibit 10-17 summarizes the results of two studies (*21, 22*) on the capacity impacts of lane blockages due to incidents, including accidents. An incident's effect on capacity depends on the proportion of the traveled roadway that is blocked and on the number of lanes on the freeway at that point.

Exhibit 10-17
Proportion of Freeway Segment Capacity Available Under Incident Conditions

Number of Lanes (One Direction)	Shoulder Disablement	Shoulder Accident	One Lane Blocked	Two Lanes Blocked	Three Lanes Blocked
2	0.95	0.81	0.35	0.00	N/A
3	0.99	0.83	0.49	0.17	0.00
4	0.99	0.85	0.58	0.25	0.13
5	0.99	0.87	0.65	0.40	0.20
6	0.99	0.89	0.71	0.50	0.26
7	0.99	0.91	0.75	0.57	0.36
8	0.99	0.93	0.78	0.63	0.41

In a blocked lane, the loss of capacity is likely to be greater than the proportion of the roadway that is blocked. A one-lane blockage on a two-lane directional freeway segment (50% of the roadway blocked) reduces capacity to 35% of the original value, not a sample. The added loss of capacity arises because drivers slow to look at the incident while they are aware of it and are slow to react to the possibility of squeezing up or move through the incident area.

The "rubbernecking" factor is also responsible for a reduction in capacity in the direction of travel opposite to that in which the accident or incident occurred. While no quantitative studies of this impact have been conducted, experience suggests that the severity of the accident or incident plays a significant role in the impact of rubbernecking. The reduction in capacity may range from 5% for a single-vehicle accident with no emergency vehicle present to as high as 27% for a multivehicle accident with several emergency vehicles.

AR0073470

Applying Capacity Reductions

There are several ways to use the information on reduced capacities discussed in this section.

Quick approximations simply require that the capacity of each freeway facility segment be estimated by using the methodologies of Chapters 11, 12, and 13; be reduced by all the impacts of work zones, weather, environment, and accidents or incidents that are present, in accord with the information provided here. The methodology continues using these reduced capacities.

If speed information is available, then the free-flow speed through the restricted capacity area can be used to select an appropriate speed–flow curve for analysis (from Chapter 11). The reduced free-flow speed results in a reduced capacity. An example of this approach is illustrated in Exhibit 10-18, which is based on speed data presented elsewhere (16, 19).

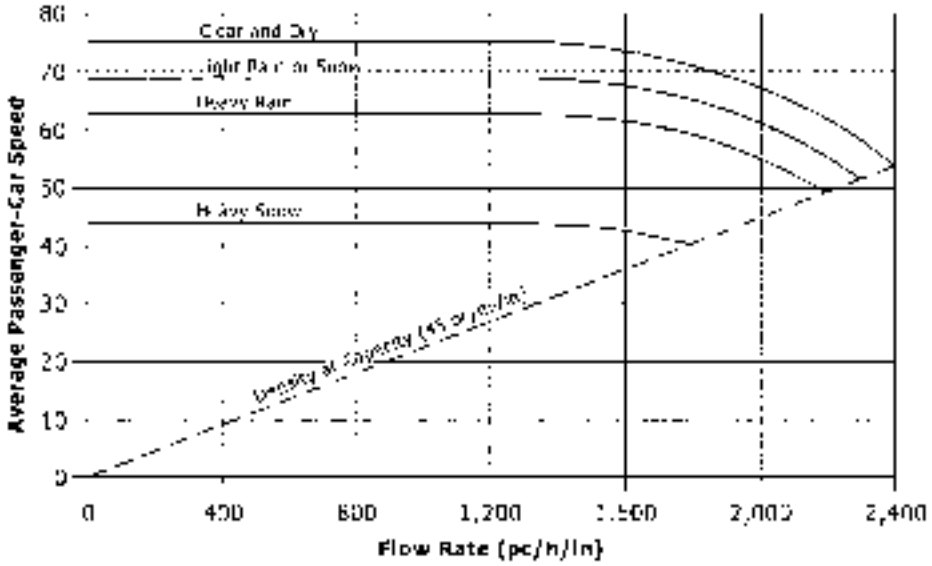

Exhibit 10-18
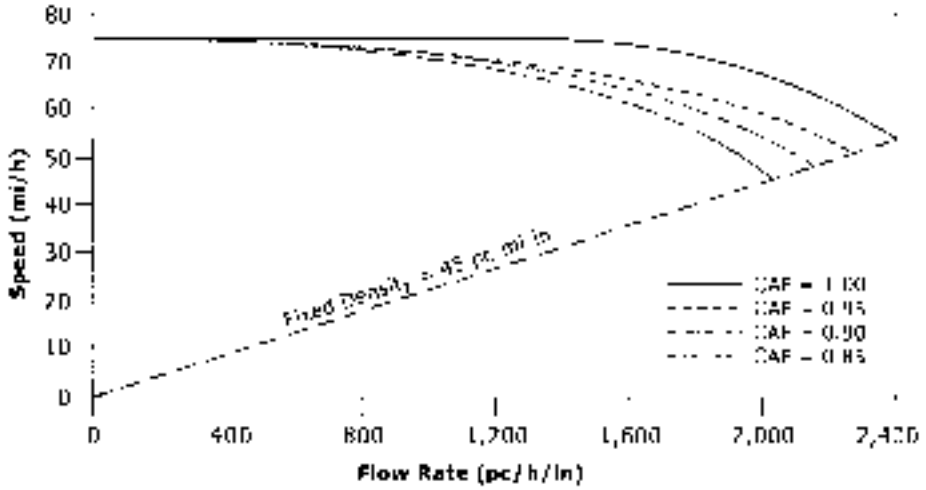
Illustration of Speed–Flow Curves for Different Weather Conditions

Note: Free-flow speed = 70 mi/h (base condition).

For most temporary capacity reductions, the only information available relates to capacity. In most of these cases, speed conditions can be reasonably estimated. For example, in construction zones, a reduced speed limit is usually posted, and lower speeds can be expected to occur, particularly when actual construction operations are taking place. Likewise, for incidents, traffic naturally slows as drivers pass the incident site where rubbernecking takes place. Exhibit 10-19 shows an example of modeling such cases on the basis of a downward-shifted speed–flow curve.

AR0073471

Exhibit 10-19
Illustration of Adjusted Speed–Flow Curves for Indicated Capacity Reductions



Note: Free-flow speed = 75 mi/h (base conditions); CAF = capacity adjustment factor (percent of nominal capacity).

If the analyst has no interest in speeds, the capacity reduction could be modeled by using a fractional number of lanes that would reflect the new capacity of the roadway rather than the actual number of lanes present. For example, in the case of a four-lane directional freeway segment with two lanes blocked, Exhibit 10-17 indicates that only 25% of capacity would be available. This segment could be modeled as if only one lane were available through the incident (even though two are actually in use).

Some of the performance measures that result from this methodology, however, rely on speed. A simple approach that does not deal with speed consequences would result in an incomplete analysis. Consequently, an approach that uses modified speed–flow curves, as illustrated here, is recommended.

Step 5: Compute Demand-to-Capacity Ratios

Each cell of the time–space domain now contains an estimate of demand and capacity. A demand-to-capacity ratio can be calculated for each cell. The cell values must be carefully reviewed to determine whether all boundary cells have v/c ratios of 1.00 or less and to determine whether any cells in the interior of the time–space domain have v/c values greater than 1.00.

If any boundary cells have a v/c ratio greater than 1.00, further analyses may be significantly flawed:

1. If any cell in the first time interval has a v/c ratio greater than 1.00, there may have been oversaturated conditions in earlier time intervals without transfer of unsatisfied demand into the time–space domain of the analysis.
2. If any cell in the last time interval has a v/c ratio greater than 1.00, the analysis will be incomplete because the unsatisfied demand in the last time interval cannot be transferred to later time intervals.
3. If any cell in the last downstream segment has a v/c ratio greater than 1.00, there may be downstream bottlenecks that should be checked before

AR0073472

proceeding with the analysis. If any cell in the first segment has a v/c ratio greater than 1.00, then oversaturation will extend upstream of the defined freeway facility, but its effects will not be analyzed within the time–space domain.

These checks do not guarantee that the boundary cells will not show v/c ratios greater than 1.00 later in the analysis. If these initial checks reveal boundary cells with v/c ratios greater than 1.00, then the time–space domain of the analysis should be adjusted to eliminate the problem.

As the analysis of the time–space domain proceeds, subsequent demand shifts may cause some boundary cell v/c ratios to exceed 1.00. In these cases, the problem should be reformulated or alternative tools applied. Most alternative tools will have the same problem if the boundary conditions experience congestion.

Another important check is to observe whether any cell in the interior of the time–space domain has a v/c ratio greater than 1.00. There are two possible outcomes:

1. If all cells have v/c ratios of 1.00 or less, then the entire time–space domain contains undersaturated flow, and the analysis is greatly simplified.
2. If any cell in the time–space domain has a v/c ratio greater than 1.00, then the time–space domain will contain both undersaturated and oversaturated cells. Analysis of oversaturated conditions is much more complex because of the interactions between freeway segments and the shifting of demand in both time and space.

If Case 1 exists, the analysis moves to Step 6A. If Case 2 exists, the analysis moves to Step 6B.

The v/c ratio for all on-ramps and off-ramps should also be examined. If an on-ramp demand exceeds the on-ramp capacity, the ramp demand flow rate should be adjusted to reflect capacity. Off ramps generally fail because of deficiencies at the ramp–street junction. They may be analyzed by procedures in Chapters 18–22, depending on the type of traffic control used at the ramp–street junction. These checks are done manually, and inputs to this methodology must be revised accordingly.

Steps 6A and 6B: Compute Undersaturated (6A)/Oversaturated (6B) Service Measures and Other Performance Measures

The analysis begins in the first cell in the upper-left corner of the time–space domain (the first segment in the first time interval) and continues downstream along the freeway facility for each segment in the first time interval. The analysis then returns to the first upstream segment in the second time interval and continues downstream along the freeway for each segment in the second time interval. This process continues until all cells in the time–space domain have been analyzed.

As each cell is analyzed in turn, its v/c ratio is checked. If the v/c ratio is 1.00 or less, the cell is not a bottleneck and is able to handle all traffic demand that

AR0073473

wishes to enter. The process is continued in the order noted in the previous paragraph until a cell with a v/c ratio greater than 1.00 is encountered. Such a cell is labeled as a bottleneck. Because it cannot handle a flow greater than its capacity, the following impacts will occur:

1. The v/c ratio of the bottleneck cell will be exactly 1.00, as the cell processes a flow rate equal to its capacity.
2. Flow rates for all cells downstream of the bottleneck must be adjusted downward to reflect the fact that not all the demand flow at the bottleneck gets through. Downstream cells are subject to demand starvation due to the bottleneck.
3. The unsatisfied demand at the bottleneck cell must be stored in the upstream segments. Flow conditions and performance measures in these upstream cells are affected. Shock wave analysis is applied to estimate these impacts.
4. The unsatisfied demand stored upstream of the bottleneck cell must be transferred to the next time interval. This transfer is accomplished by adding the unsatisfied demand by desired destination to the origin–destination table of the next time interval.

This four-step process is implemented for each bottleneck encountered, following the specified sequence of cell analyses. If no bottlenecks are identified, the entire domain is undersaturated, and the sequence of steps for oversaturated conditions is not applied.

If a bottleneck is severe, the storage of unsatisfied demand may extend beyond the upstream boundary of the freeway facility or beyond the last time interval of the time–space domain. In such cases, the analysis will be flawed, and the time–space domain should be reconstructed.

After all demand shifts (in the case of one or more oversaturated cells) are estimated, each cell is analyzed by the methodologies of Chapter 11, Basic Freeway Segments; Chapter 12, Freeway Weaving Segments; and Chapter 13, Freeway Merge and Diverge Segments. Facility service and performance measures may then be estimated.

Undersaturated Conditions

For undersaturated conditions, the process is straightforward. Because there are no cells with v_i/c_i ratios greater than 1.00, the flow rate in each cell, v_i, is equal to the demand flow rate, v_i. Each segment analysis using the methodologies of Chapters 11, 12, and 13 will result in estimating a density, D_i, and a space mean speed, S_i.

When the analysis moves from isolated segments to a system, additional constraints may be necessary. A maximum-achievable-speed constraint is imposed to limit the prediction of speeds on segments downstream of a segment experiencing low speeds. This constraint prevents large speed fluctuations from segment to segment when the segment methodologies are directly applied. This process results in some changes in the speeds and densities predicted by the segment methodologies.

AR0073474

For each time interval, Equation 10-3 is used to estimate the average density for the defined freeway facility. This result is compared with the criteria of Exhibit 10-7 to determine the facility LOS for the time period. Each time period will have a separate LOS. Although LOS is not averaged over time intervals, if desired, density can be averaged over time intervals.

Oversaturated Conditions

Once oversaturation is encountered, the methodology changes its temporal and spatial units of analysis. The spatial units become nodes and segments, and the temporal unit moves from a time interval of 15 min to smaller time periods, as recommended in Chapter 25, Freeway Facilities Supplemental.

Exhibit 10-20 illustrates the node–segment concept. A node is defined as the junction of two segments. Given that there is a node at the beginning and end of the freeway facility, there will always be one more node than the number of segments on the facility.

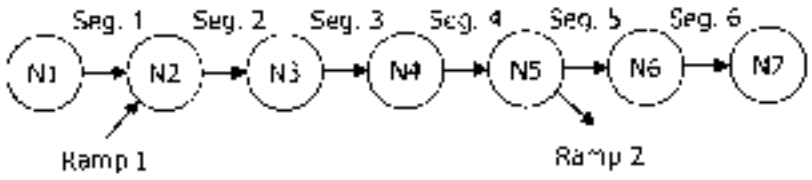


Exhibit 10-20
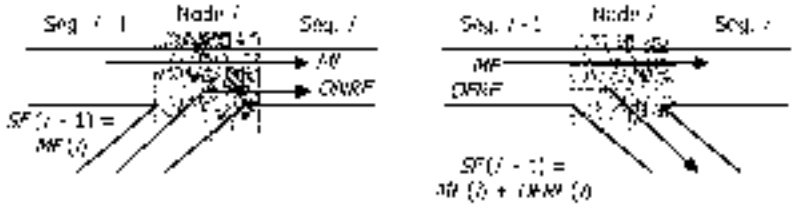
Node–Segment Representation of a Freeway Facility

The numbering of nodes and segments begins at the upstream end of the defined freeway facility and moves to the downstream end. The segment upstream of node i is numbered $i - 1$, and the downstream segment is numbered i, as shown in Exhibit 10-21.



Note: SF = segment flow, MF = mainline flow, ORRF = on-ramp flow, and OFRF = off-ramp flow.

Exhibit 10-21
Mainline and Segment Flow at On- and Off-Ramps

The oversaturated analysis moves from the first node to each downstream node for a time step. After the analysis for the first time step is complete, the same node analysis is performed for each subsequent time step.

When oversaturated conditions exist, many flow variables must be adjusted to reflect the upstream and downstream effects of bottlenecks. These adjustments are explained in general terms in the sections that follow and are fully detailed in Chapter 25.

Flow Fundamentals

As noted previously, segment flow rates must be calculated for each time step. They are used to estimate the number of vehicles on each segment at the

AR0073475

end of every time step. The number of vehicles on each segment is used to track queue accumulation and discharge and to estimate the average segment density.

The conversion from standard 15-min time intervals to time steps (of lesser duration) occurs during the first oversaturated interval. Time steps are then used until the analysis is complete. This transition to time steps is critical because, at certain points in the methodology, future performance is estimated from past performance of an individual variable. Use of time steps also allows for a more accurate estimation of queues.

Service and other performance measures for oversaturated conditions use a simplified, linear flow–density relationship, as detailed in Chapter 25.

Segment Initialization

To estimate the number of vehicles on each segment for each time step under oversaturated conditions, it is necessary to begin the process with the appropriate number of vehicles in each segment. Determining this number is referred to as *segment initialization*.

A simplified queuing analysis is initially performed to account for the effects of upstream bottlenecks. The bottlenecks limit the number of vehicles that can proceed downstream.

To obtain the proper number of vehicles on each segment, the expected demand is calculated from the demands for and capacities of the segment, including the effects of all upstream segments. The expected demand represents the flow that would arrive at each segment if all queues were stacked vertically (i.e., if the queues had no upstream impacts). For all segments upstream of a bottleneck, the expected demand will equal the actual demand.

For the bottleneck segment and all further downstream segments, a capacity restraint is applied at the bottleneck when expected demand is computed. From the expected segment demand, the background density can be obtained for each segment by using the appropriate estimation algorithms from Chapters 11, 12, and 13.

Mainline Flow Calculation

Flows analyzed in oversaturated conditions are calculated for every time step and are expressed in vehicles per time step. They are analyzed separately on the basis of the origin and destination of the flow across the node. The following flows are defined:

1. The flow from the mainline upstream segment $i-1$ to the mainline downstream segment i is the mainline flow (MF_i).
2. The flow from the mainline to an off-ramp is the off-ramp flow (OFF_i).
3. The flow from an on-ramp to the mainline is the on-ramp flow (ONF_i).

Each of these flows is illustrated in Exhibit 10-21.

Mainline Input

The mainline input is the number of vehicles that wish to travel through a node during the time step. The calculation includes the effects of bottlenecks

AR0073476

upstream of the subject node. The effects include the metering of traffic during queue accumulation and the presence of additional vehicles during queue discharge.

The mainline input is calculated by taking the number of vehicles entering the node upstream of the analysis node, adding on-ramp flows or subtracting off-ramp flows, and adding the number of unserved vehicles on the upstream segment. The result is the maximum number of vehicles that desire to enter a node during a time step.

Mainline Output

The mainline output is the maximum number of vehicles that can exit a node, constrained by downstream bottlenecks or by merging traffic. Different constraints on the output of a node result in three different types of mainline outputs (M01, M02, and M03).

- *Mainline output from ramp flow (M01):* M01 is the constraint caused by the flow of vehicles from an on-ramp. The capacity of an on-ramp flow is shared by two competing flows: flow from the on-ramp and flow from the mainline. The total flow that can pass the node is estimated as the minimum of the segment capacity and the mainline outputs (M02 and M03) calculated in the preceding time step.
- *Mainline output from segment density (M02):* The output of mainline flow through a node is also constrained by the growth of queues on the downstream segment. The presence of a queue limits the flow into the segment once the queue reaches its upstream end. The queue position is calculated by shock wave analysis. The M02 limitation is determined first by calculating the maximum number of vehicles allowed on a segment at a given queue density. The maximum flow that can enter a queued segment is the number of vehicles leaving the segment plus the difference between the maximum number of vehicles allowed on a segment and the number of vehicles already on the segment. The queue density is determined from the lower congested portion of the density–flow relationship shown in Chapter 25.
- *Mainline output from front clearing queue (M03):* The final limitation on exiting mainline flows at a node is caused by front clearing downstream queues. These queues typically occur when temporary incidents clear. Two conditions must be satisfied: (a) the segment capacity (minus the on-ramp demand, if present) for the current time interval must be greater than the segment capacity (minus on-ramp demand) in the preceding time interval, and (b) the segment capacity minus the ramp demand for the current time interval must be greater than the segment demand in the same time interval. Front-clearing queues do not affect the segment throughput (which is limited by queue throughput) until the recovery wave has reached the upstream end of the segment. The shock wave speed is estimated from the slope of the line connecting the bottleneck throughput and the segment capacity points.

AR0073477

Mainline Flow

The mainline flow at node *i* is the minimum of the following variables:

- Node *i* mainline input,
- Node *i* MLI2,
- Node *i* MLI3,
- Segment *i* − 1 capacity, and
- Segment *i* capacity.

Determining On-Ramp Flow

The on-ramp flow is the minimum of the on-ramp input and output. Ramp input in a time step is the ramp demand plus any unserved ramp vehicles from a previous time step.

On-ramp output is limited by the ramp roadway capacity and the ramp-metering rate. It is also affected by the volumes on the mainline segments. The latter is a very complex process that depends on the various flow combinations on the segment, the segment capacity, and the ramp roadway volumes. Details of the calculations are presented in Chapter 25.

Determining Off-Ramp Flow

The off-ramp flow is determined by calculating a diverge percentage based on the segment and off-ramp demands. The diverge percentage varies only by time interval and remains constant for vehicles that are associated with a particular time interval. If there is an upstream queue, then traffic to the off-ramp may be metered. This will cause a decrease in the off-ramp flow. When vehicles that were metered arrive in the next time interval, they use the diverge percentage associated with the preceding time interval. This methodology ensures that all off-ramp vehicles prevented from exiting during the presence of a bottleneck are appropriately discharged in later time intervals.

Determining Segment Flow

Segment flow is the number of vehicles that flow out of a segment during the current time step. These vehicles enter the current segment either to the mainline or to an off-ramp at the current node as shown in Exhibit 10-20. The number of vehicles on each segment in the current time step is calculated with the following information:

- The number of vehicles that were in the segment in the previous time step,
- The number of vehicles that entered the segment in the current time step, and
- The number of vehicles that can leave the segment in the current time step.

Because the number of vehicles that leave a segment must be known, the number of vehicles on the current segment cannot be determined until the upstream segment is analyzed.

AR0073478

The number of unserved vehicles stored on a segment is calculated as the difference between the number of vehicles on the segment and the number of vehicles that would be on the segment at the background density.

Determining Segment Service Measures

In the last time step of a time interval, the segment flows in each time step are averaged over the time interval, and the service measures for each segment are calculated. If there were no queues on a particular segment during the entire time interval, then the performance measures are calculated from Chapters 11, 12, and 13 as appropriate.

If there was a queue on the current segment during the time interval, then the performance measures are calculated in four steps:

1. The average number of vehicles over a time interval is calculated for each segment.
2. The average segment density is calculated by taking the average number of vehicles in all time steps (in the time interval) and dividing it by the segment length.
3. The average speed on the current segment during the current time interval is calculated as the ratio of segment flow to density.
4. The final segment performance measure is the length of the queue at the end of the time interval (if one exists), which is calculated by using shock wave theory.

On-ramp queue lengths can also be calculated. A queue will form on the on-ramp roadway only if the flow is limited by a meter or by freeway traffic in the gore area. If the flow is limited by the ramp roadway capacity, unserved vehicles will be stored on a facility upstream of the ramp roadway, most likely a surface street. The methodology does not account for this delay. If the queue is on a ramp roadway, its length is calculated by using the difference in background and queue densities.

Step 7: Compute Freeway Facility Service Measures and Other Performance Measures by Time Interval

The previously discussed traffic performance measures can be aggregated over the length of the defined freeway facility for each time interval. Aggregations over the entire time–space domain of the analysis are also mathematically possible, although LOS is defined only for 15-min time intervals.

Freeway facility LOS is defined for each time interval included in the analysis. An average density for each time interval, weighted by length of segments and numbers of lanes in segments, is calculated (with Equation 10-2) and used to compare with the criteria of Exhibit 10-7.

AR0073479

3. APPLICATIONS

Specific computational steps for the freeway facility methodology were conceptually discussed and presented in this chapter's methodology section. Additional computational details are provided in Chapter 25, Freeway Facilities: Supplemental.

This chapter's methodology is sufficiently complex to require software for its application. Even for fully undersaturated analyses, the number and complexity of computations make it difficult and extremely time-consuming to analyze a case manually. Oversaturated analyses are considerably more complex, and manual solutions would be impractical. The computational engine for this methodology is FRESIM. A complete user's guide and executable spreadsheet are available in the Technical Reference Library in Volume 4.

OPERATIONAL ANALYSIS

The only mode in which the methodology can be directly implemented is operational analysis—that is, given a complete description of a freeway facility, its component segment geometrics, and all relevant demand flow rates, a complete analysis is conducted of each segment and of the freeway facility, by time interval. Outputs will include segment flow rates, densities, and average speeds as well as average facility density and speed for each time interval. By using the estimated facility density for each time interval, a facility LOS can be assigned.

Exhibit 10-22 shows the data inputs that are required for an operational analysis of a freeway facility.

Exhibit 10-22
Required Input Data for Freeway Facility Analysis

Geometric Data for Each Section
• Section length (ft)
• Mainline number of lanes
• Mainline average lane width (ft)
• Mainline lateral clearance (ft)
• Terrain (level, rolling, or mountainous), or specific grade (or grade length in mi)
• Ramp number of lanes
• Ramp acceleration or deceleration lane length (ft)
• Existence of independent HOV lane
Traffic Characteristic Data for Each Segment
• Mainline free-flow speed (mph), optional
• Vehicle occupancy (passengers/veh)
• Percent trucks and buses (%)
• Percent RVs (%)
• Driver population (commuter or recreational)
• Ramp free-flow speeds (mi/h)
Demand Data for Each Segment
• Mainline entry demand for each time interval (veh/h)
• On-ramp demands for each time interval (veh/h)
• Off-ramp demands for each time interval (veh/h)
• Weaving demands on weaving segments, by movement (veh/h)
• HOV lane demand (veh/h), if present

Where all data are not readily available or collectable, the analysis may be supplemented by using consistent default values for each segment. Lists and discussions of default values are found in Chapter 11, Basic Freeway Segments.

AR0073480

Chapter 12, Freeway Weaving Segments, and Chapter 13, Freeway Merge and Diverge Segments.

Performance measures output by the methodology for individual segments and the facility (for a given time interval) include the following:

- Average speed (mi/h),
- Average density (pc/mi/ln),
- Vehicle miles of travel,
- Vehicle hours of travel, and
- Travel time (min/veh).

Chapter 23 details facility-wide performance measure calculations by time interval.

PLANNING, PRELIMINARY ENGINEERING, AND DESIGN ANALYSIS

This methodology cannot be directly used in planning, preliminary engineering, and design applications. However, for generalized planning, Exhibit 10-5 (urban freeways) and Exhibit 10-9 (rural freeways) provide daily service-volume tables for a variety of typical freeway conditions. These tables may be applied for general evaluations of a number of freeway facilities in a specified region. They should not be used for directly evaluating a specific freeway facility or for developing detailed facility improvement plans. A full operational analysis would normally be applied to any freeway facility identified as potentially needing improvement.

Preliminary engineering and design applications of the methodology are possible by using the segment procedures described in Chapters 11, 12, and 13. Various geometric scenarios can be evaluated and compared by using a travel demand matrix and the facility methodology on the basis of the segment results.

TRAFFIC MANAGEMENT STRATEGIES

The freeway facilities methodology has incorporated procedures for assessing a variety of traffic management strategies. The methodology permits modifying previously calculated demands or capacities (or both) within the time–space domain to assess a traffic management strategy or a combination of strategies.

1. A growth factor parameter has been incorporated to evaluate traffic performance when traffic demands are higher or lower than the demand calculated from the traffic counts. This parameter would be used to undertake a sensitivity analysis of the effect of demand on freeway performance and to evaluate future scenarios. In these cases, all cell demand estimates are multiplied by the growth factor parameter.
2. The effect of a predetermined ramp-metering plan can be evaluated by modifying the ramp roadway capacities. The capacity of each entrance ramp in each time interval is changed to the desired metering rate. This feature permits evaluating a predetermined ramp-metering plan and experimenting to obtain an improved ramp-metering plan.

AR0073481

3. Freeway design improvements can be evaluated with this methodology by modifying the design features of any portion of the freeway facility. For example, the effect of adding an auxiliary lane at a critical location or adding merging or diverging lanes can be assessed.
4. Reduced-capacity situations can be investigated. The capacity in any cell or cells of the time–space domain can be reduced to represent situations such as construction and maintenance activities, adverse weather, and traffic accidents and vehicle breakdowns.
5. User demand responses such as spatial, temporal, modal, and total demand responses caused by a traffic management strategy are not automatically incorporated into the methodology. Or, viewing the new freeway traffic performance results, the user can modify the demand input manually to evaluate the effect of anticipated demand responses.

USE OF ALTERNATIVE TOOLS

General guidance for the use of alternative traffic analysis tools for capacity and LOS analysis is provided in Chapter 6, HCM and Alternative Analysis Tools. This section contains specific guidance for applying alternative tools to the analysis of freeway facilities. Additional information on this topic may be found in Chapter 25, Freeway Facilities: Supplemental.

Strengths of the HCM Procedure

This chapter's procedures were based on extensive research supported by a significant quantity of field data. They have evolved over a number of years and represent a consensus of experts. Specific strengths of the HCM freeway facilities procedures include the following:

- They provide more detailed algorithms for considering geometric elements of the facility (such as lane and shoulder width).
- They provide capacity estimates for each segment of the facility, which simulation tools do not provide directly (and in some cases may require as an input).
- The capacity can be explicitly adjusted to account for weather conditions, lighting conditions, work zone setup and activity, and incidents.
- The calculation of key performance measures, such as speed and density, is transparent. Simulation tools often use statistics accumulated over the simulation period to derive various link or time-period-specific results, and the derivation of these results may not be obvious. Thus, the user of a simulation tool must know exactly which measure is being reported (e.g., space mean speed versus time mean speed). Furthermore, simulation tools may apply these measures in ways different from the HCM to arrive at other measures.

AR0073482

Limitations of the HCM Procedures That Might Be Addressed by Alternative Tools

Freeway facilities can be analyzed with a variety of stochastic and deterministic simulation tools. These tools can be useful in analyzing the extent of congestion when there are failures within the simulated facility range and when interaction with other freeway segments and other facilities is present.

Exhibit 10-23 provides a list of the limitations stated earlier in this chapter, along with their potential for improved treatment by alternative tools.

Exhibit 10-23
Limitations of the HCM Freeway Facilities Analysis Procedure

Limitation	Potential for Improved Treatment by Alternative Tools
Changes in travel time caused by vehicles using alternate routes	Modeled explicitly by dynamic traffic assignment tools
Multiple overlapping bottlenecks	Modeled explicitly by simulation tools
Just-demand responses (spatial, temporal, modal)	Modeled explicitly by dynamic traffic assignment tools
System-wide oversaturated flow conditions	Modeled explicitly by simulation tools
First/last time interval or first/last segment demand-to-capacity ratio > 1.0	Modeled explicitly by simulation tools, except that a simulation analysis may also be inaccurate if it does not fully account for a downstream bottleneck that causes congestion in the last segment during the last time period
Interaction between managed lanes and mixed-flow lanes	Modeled explicitly by some simulation tools

Additional Features and Performance Measures Available from Alternative Tools

This chapter provides a methodology for estimating a variety of performance measures for individual segments along a freeway facility, and for the entire facility, given each segment's traffic demand and characteristics. The following performance measures are reported by the freeway facilities procedure:

- Travel time,
- Free-flow travel time,
- Traffic delay,
- Vehicle miles of travel,
- Person miles of travel,
- Speed, and
- Density (segment only).

Alternative tools can offer additional performance measures, such as queue lengths, fuel consumption, vehicle emissions, and operating costs. As with most other procedural chapters in the HCM, simulation outputs—especially graphics-based presentations—may provide details on point problems that might go unnoticed with a macroscopic analysis.

Development of HCM-Compatible Performance Measures Using Alternative Tools

LOS for all types of freeway segments is estimated by the density of traffic (pc/mi/ln) on each segment. The guidance provided in Chapter 12, Basic Freeway

AR0073483

segments, for developing compatible density estimates applies to freeway facilities as well.

With the exception of true flow travel time, the additional performance measures listed above that are produced by the procedure in this chapter are also produced by typical simulation tools. For the most part, the definitions are compatible, and, subject to the precautions and calibration requirements that follow, the performance measures from alternative tools may be considered equivalent to those that are produced by the procedures in this chapter.

Conceptual Differences Between the HCM and Simulation Modeling That Preclude Direct Comparison of Results

To better determine when a simulation of a freeway facility may be more appropriate than an HCM analysis, the fundamental differences between the two approaches must be understood. The HCM and simulation analysis approaches are reviewed in the following subsections.

HCM Approach

The HCM analysis procedure uses one of two approaches—one for undersaturated conditions and one for oversaturated conditions. For undersaturated conditions—that is, v/c less than 1.0 for all segments and time periods—the approach is generally disaggregate. In other words, the facility is subdivided into segments corresponding to basic freeway, weaving, and merge/diverge segments, and the LOS results are reported for individual segments on the basis of the analysis procedures of Chapters 11, 12, and 13, respectively. However, LOS results are not reported for the facility as a whole.

For oversaturated conditions, the facility is analyzed in a different manner. First, the facility is considered in its entirety rather than as the individual segment level. Second, the analysis time interval, typically 15 min, is subdivided into time steps of 15 to 60 s, depending on the length of the shortest segment. This approach is necessary so that flows can be reduced to capacity levels at bottleneck locations and queues can be tracked in space and time. For oversaturated segments, the average segment density is calculated by dividing the average number of vehicles for all time steps (in the time interval) by the segment length. The average segment speed is calculated by dividing the average segment flow rate by the average segment density. Facility/area performance measures are calculated by aggregating segment performance measures across space and time, as outlined in Chapter 25. A LOS for the facility is assigned on the basis of density for each time interval.

When the oversaturation analysis procedure is applied, if any segment is undersaturated for an entire time interval, its performance measures are calculated as occurring to the appropriate procedure in Chapters 11, 12, and 13.

Simulation Approach

Simulation tools model the facility in its entirety and from that perspective have some similarity to the oversaturated analysis approach of the HCM. Microscopic simulation tools operate similarly under both saturated and undersaturated conditions, tracking each vehicle through time and space and

AR0073484

generally handling the accumulation and queuing of vehicles in saturated conditions in a realistic manner. Macroscopic simulation tools vary in their treatment of saturated conditions. Some tools do not handle oversaturated conditions at all, while others may queue vehicles in the vertical, rather than horizontal, dimension. These tools may still provide reasonably accurate results under slightly oversaturated conditions, but the results will clearly be invalid for heavily congested conditions.

The treatment of oversaturated conditions is a fundamental issue that must be understood when considering whether to apply simulation in lieu of the HCM for analysis of congested conditions. A review of simulation modeling approaches is beyond the scope of this document. More detailed information on the topic may be found in the Technical Reference Library in Volume 4.

Adjustment of Simulation Parameters to the HCM Results

Some calibration is generally required before an alternative tool can be used effectively to supplement or replace the HCM procedure. The following subsections discuss key variables that should be checked for consistency with the HCM procedure values.

Capacity

In the HCM, capacity is a function of the specified free-flow speed (which can be adjusted by lane width, shoulder width, and ramp density). In a simulation tool, capacity is typically a function of the specified minimum vehicle entry headway (into the system) and car-following parameters (assuming microscopic simulation).

While the determination of capacity for a basic freeway segment is clearly described in Chapter 12, this chapter does not offer specific guidance on determining the appropriate capacity for different segment types within a facility, other than to refer the reader to the individual chapters (basic segments, weaving segments, merge segments, diverge segments) for appropriate capacity values. The HCM specifies the capacity of a freeway facility in units of veh/h, rather than pc/h.

In macroscopic simulation tools, capacity is generally an input. Thus, for this situation, it is straightforward to match the simulation capacity to the HCM capacity. Microscopic simulation tools, however, do not have an explicit capacity input. Most microscopic tools provide an input that affects the minimum separation for the generation of vehicles into the system. Therefore, specifying a value of 1.5 s for this input will result in a maximum vehicle entry rate of 2,400 (3,600/1.5) veh/h/ln. Once vehicles enter the system, vehicle headways are governed by the car-following model. Thus, given other factors and car following model constraints, the maximum throughput on any one segment may not reach this value. Consequently, some experimenting is usually necessary to find the right minimum entry separation value to achieve a capacity value comparable with that in the HCM. Again, the analyst needs to be careful of the units being used for capacity in making comparisons.

AR0073485

The other factor to be aware of is that, while geometric factors such as lane and shoulder width affect the free-flow speed (which in turn affects capacity) in the HCM procedure, some simulation tools do not account for these effects, or they may account for other factors, such as horizontal curvature, that the HCM procedure does not consider.

Lane Distribution

In the HCM procedure, there is an implicit assumption that, for any given vehicle demand, the vehicles are evenly distributed across all lanes of a basic freeway segment. For merge and diverge segments, the HCM procedure includes calculations to determine how vehicles are distributed across lanes as a result of merging or diverging movements. For weaving segments, there is not an explicit determination of flow rates in particular lanes, but consideration of weaving and nonweaving flows and the number of lanes available for each is an essential element of the analysis procedure.

In simulation tools, the distribution of vehicles across lanes is typically specified only for the entry point of the network. Once vehicles have entered the network, they are distributed across lanes according to car-following and lane-changing logic. The input value should reflect field data if they are available. If field data indicate an imbalance of flows across lanes, this situation may lead to a difference between the HCM and simulation results. If field data are not available, specifying an even distribution of traffic across all lanes is probably reasonable for networks that begin with a long basic segment. If there is a ramp junction within a short distance downstream of the entry point of the network, setting the lane distribution values to be consistent with those from Chapter 13 of the HCM will likely yield more consistent results.

Traffic Stream Composition

The HCM deals with the presence of non-passenger car vehicles in the traffic stream by applying passenger car equivalent values. These values are based on the percentage of trucks, buses, and RVs in the traffic stream as well as type of terrain (grade percent and its length). Thus, the traffic stream is converted into some equivalent number of passenger cars only, and the analysis results are based on flow rates in these units.

In the case of macroscopic-based simulators, the generated vehicle type percentages may also approximate the specified percentages.

Simulation tools deal with the traffic stream composition just as it is specified; that is, the specific percentages of each vehicle type are generated into and moved through the system according to their specific vehicle attributes (e.g., acceleration and deceleration capabilities). Thus, simulation, particularly microscopic simulation, results likely better reflect the effects of non-passenger car vehicles on the traffic stream. Although in some instances the passenger car equivalent values contained in the HCM were developed from simulation data, simplifying assumptions made to make them implementable in an analytical procedure result in some loss of fidelity in the treatment of different vehicle types.

Furthermore, it should be recognized that the HCM procedure does not explicitly account for differences in driver types. Microscopic simulation tools explicitly provide for a range of driver types and allow a number of factors

AR0073486

relative to driver type to be modified (e.g., free flow speed, gap acceptance threshold). However, it should also be recognized that the empirical data some HCM procedures are based on include the effects of the various driver types present in traffic streams.

Free-Flow Speed

In the HCM, free flow speed is either measured in the field or estimated with calibrated predictive algorithms. In simulation, free-flow speed is almost always an input value. Where field measurements are not available, simulation users may wish to use the HCM predictive algorithms to estimate free-flow speed.

Step-by-Step Recommendations for Applying Alternative Tools

General guidance for applying alternative tools is provided in Chapter 6, HCM and Alternative Analysis Tools. The chapters that cover specific types of freeway segments offer more detailed step by step guidance specific to those segments. All the segment-specific guidance applies to freeway facilities, which are configured as combinations of different segments.

The first step is to determine whether the facility can be analyzed satisfactorily by the procedures described in this chapter. If the facility contains geometric or operational elements beyond the scope of these procedures, then an alternative tool should be selected. The steps involved in the application will depend on the reason(s) for choosing an alternative tool. In some cases, the step by step segment guidance will cover the situation adequately. In more complex cases (e.g., those not involving integrated analysis of a freeway corridor), more comprehensive guidance from one or more documents in the Technical Reference Library in Volume 4 may be needed.

Sample Calculations Illustrating Alternative Tool Applications

The limitations of this chapter's procedures are mainly related to the lack of a comprehensive treatment of the interaction between segments and facilities. Many of these limitations can be addressed by simulation tools, which generally take a more integrated approach to the analysis of complex networks of freeways, ramps, and surface street facilities. Supplemental examples illustrating interactions between segments are presented in Chapter 26, Freeway and Highway Segments: Supplemental, and Chapter 30, Interchange Ramp Terminals: Supplemental. A comprehensive example of the application of simulation tools to a major freeway reconstruction project is presented as Case Study 6 in the HCM Applications Guide located in Volume 4.

AR0073487

4. EXAMPLE PROBLEMS

Exhibit 10-24
List of Example Problems

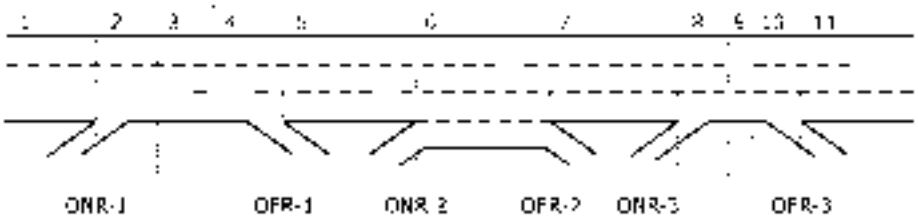
Example Problem	Description	Application
1	Evaluation of an undersaturated facility	Operational analysis
2	Evaluation of an oversaturated facility	Operational analysis
3	Capacity improvements to an oversaturated facility	Operational analysis

EXAMPLE PROBLEM 1: EVALUATION OF AN UNDERSATURATED FACILITY

The Facility

The subject of this operational analysis is an urban freeway facility in mid-city and composed of 11 individual analysis segments, as shown in Exhibit 10-25.

Exhibit 10-25
Freeway Facility in Example Problem 1



The facility has three on-ramps and three off-ramps. Geometric details are given in Exhibit 10-26.

Exhibit 10-26
Geometry of Directional Freeway Facility for Example Problem 1

Segment No.	1	2	3	4	5	6	7	8	9	10	11
Segment type	B	ONR	B	OFR	B	B or W	O	ONR	R	OFR	B
Segment length (ft)	5,280	1,500	2,200	1,500	5,280	2,640	5,280	1,140	360	1,140	5,280
No. of lanes	3	3	3	3	3	4	3	3	3	3	3

Note: B = basic freeway segment, W = weaving segment, ONR = on-ramp (merge) segment, OFR = off-ramp (diverge) segment, R = overlapping ramp segment.

The on- and off-ramps in Segment 5 are connected by an auxiliary lane and the segment may therefore operate as a weaving segment, depending on traffic patterns. The separation of the on-ramp in Segment 8 and the off-ramp in Segment 10 is less than 3,000 ft. Since the ramp influence area of on-ramps and off-ramps is 1,500 ft, according to Chapter 13, the segment affected by both ramps is analyzed as a separate overlapping ramp segment (Segment 9), labeled "R."

The analysis question at hand is the following: What is the operational performance and LOS of the directional freeway facility shown in Exhibit 10-25?

AR0073488

The Facts

In addition to the information contained in Exhibit 10-25 and Exhibit 10-26, the following characteristics of the freeway facility are known:

Heavy vehicles – 5% trucks, 0% RVs (all movements);
Driver population – regular commuters;
FFS – 60 mi/h (all mainline segments);
Ramp *FFS* – 40 mi/h (all ramps);
Acceleration lane length – 500 ft (all ramps);
Deceleration lane length – 500 ft (all ramps);
$D_{1,4}$ – 191 pc/mi/ln;
$c_{h,1}$ – 2,300 pc/h/ln (for *FFS* = 60 mi/h);
L_1 – 1,940 ft (for Weaving Segment 6);
TRD – 10 ramp/mi;
Terrain – level; and
Analysis duration – 75 min (divided into five 15-min intervals).

Comments

The facility was segmented into analysis segments on the basis of the guidance given in this chapter. The facility shown in Exhibit 10-25 initially depicts seven freeway sections (measured between ramps) that are divided into 11 analysis segments. The facility contains each of the possible segment types for illustrative purposes, including basic segment (B), weaving segment (W), merge segment (ONR), diverge segment (OFR), and overlapping ramp segment (R). The input data contain the required information needed for each of the segment methodologies.

The classification of the weaving Segment 6 is preliminary until it is determined whether the segment operates as a weave. For this purpose, the short length must be compared with the maximum length for weaving analysis to determine whether the Chapter 12, Weaving Segments, methodology or the Chapter 13, Basic Freeway Segments, methodology is applicable. The short length of the weaving segment used for calculation is shorter than the weaving influence area over which the calculated speed and density measures are applied.

Chapter 7 must be consulted to find appropriate values for the heavy vehicle adjustment factor f_{HV} and the driver population adjustment factor f_p. FREEVAL-2010 automatically determines these adjustment factors for general terrain conditions, but user input is needed for specific upgrades and composite grades.

All input parameters have been specified, so default values are not needed. Fifteen-minute demand flow rates are given in vehicles per hour under prevailing conditions. These demands must be converted to passenger cars per

AR0073489

hour under equivalent ideal conditions for use in the parts of the methodology related to segment LOS estimation.

Step 1: Input Data

Traffic demand inputs for all 11 segments and five analysis intervals are given in Exhibit 10-27.

Exhibit 10-27
Demand Inputs for Example Problem 1

Time Step (15 min)	Entering Flow Rate (veh/h)	Ramp Flow Rates by Time Period (veh/h)						Exiting Flow Rate (veh/h)
		ONR1	ONR2*	ONR3	OFR1	OFR2	OFR3	
1	4,200	410	590 (30)	490	270	360	270	5,040
2	4,955	540	720 (180)	540	360	360	270	5,765
3	5,735	630	810 (150)	630	270	360	450	6,715
4	4,585	360	360 (90)	450	270	360	270	4,965
5	3,785	180	270 (90)	270	270	180	180	3,875

* Numbers in parentheses indicate OFR 2 to OFR 2 demand flow rates passing Segment 6.

The volumes in Exhibit 10-27 represent the 15-min demand flow rates on the facility as determined from field observations or other sources. The actual volume served in each segment will be determined by the methodology. The demand flows are given for the extended time–space domain, consistent with this chapter's recommendations. Peaking occurs in the third 15-min period. Since inputs are in the form of 15-min flow rates, no peak hour factor adjustment is necessary. Additional geometric and traffic-related inputs are as specified in Exhibit 10-25 and the facts section of the problem statement.

Step 2: Demand Adjustments

The traffic flows in Exhibit 10-27 are already given in the form of actual demands. Therefore, no additional demand adjustment is necessary, since the flows represent true demand. Demand adjustment is necessary only if field-measured volumes are used that may be affected by upstream congestion (bottlenecks) on the facility. The methodology (and FREEVAL-2010) assumes that the user inputs true demand flows.

Step 3: Compute Segment Capacities

Segment capacities are determined by using the methodologies of Chapter 11 for basic freeway segments, Chapter 12 for weaving segments, and Chapter 13 for merge and diverge segments. The resulting capacities are shown in Exhibit 10-28. Since the capacity of a weaving segment depends on traffic patterns, including the weaving ratio, it varies by time period. The remaining segment capacities are constant in all five time intervals. The capacities for Segments 1–5 and 7–11 are the same, since the segments have the same basic cross-section. The units shown are in vehicles per hour.

Exhibit 10-28
Segment Capacities for Example Problem 1

Time Step	Capacities (veh/h) by Segment										
	1	2	3	4	5	6	7	8	9	10	11
1						8,252					
2						8,761					
3	8,712	8,712	8,712	8,712	8,712	8,303	8,712	8,712	8,712	8,712	8,712
4						8,362					
5						8,342					

AR0073490

Step 4: Adjust Segment Capacities

This step typically allows the user to adjust capacities of specific segments or time periods to model the effects of short-term work zones, long-term construction, inclement weather conditions, or incidents. Since it's the base scenario in this sequence of example problems, no additional capacity adjustments are performed.

Step 5: Compute Demand-to-Capacity Ratios

The demand-to-capacity ratios are calculated from the demand flows in Exhibit 10-27 and from the segment capacities in Exhibit 10-28.

Exhibit 10-29
Segment Demand-to-Capacity Ratios for Example Problem 1

Time Step	Demand-to-Capacity Ratios by Segment										
	1	2	3	4	5	6	7	8	9	10	11
1	0.67	0.74	0.74	0.74	0.70	0.63	0.72	0.75	0.75	0.79	0.75
2	0.74	0.82	0.82	0.82	0.76	0.71	0.82	0.90	0.90	0.90	0.86
3	0.78	0.87	0.87	0.87	0.83	0.77	0.90	0.95	0.95	0.99	0.92
4	0.70	0.75	0.75	0.75	0.71	0.61	0.71	0.78	0.78	0.78	0.74
5	0.56	0.59	0.59	0.59	0.55	0.47	0.55	0.60	0.60	0.60	0.58

The computed demand-to-capacity ratio matrix in Exhibit 10-29 shows no segments with a v/c ratio greater than 1.0 in any time interval. Consequently, the facility is categorized as *globally undersaturated* and the analysis proceeds with computing the undersaturated service measures in Step 6a. Further, it is expected that no queuing will occur on the facility and that the volumes served in each segment is identical to the input demand flows. Consequently, the matrix of volume-to-capacity ratios would be identical to the demand-to-capacity ratios in Exhibit 10-29. The resulting matrix of volumes served by segment and time interval is shown in Exhibit 10-30.

Exhibit 10-30
Volume-Served Matrix for Example Problem 1

Time Step	Volumes Served (veh/h) by Segment										
	1	2	3	4	5	6	7	8	9	10	11
1	4,930	4,995	4,995	4,995	4,685	5,275	4,865	5,315	5,315	5,315	5,045
2	4,995	5,495	5,495	5,495	5,135	5,855	5,495	6,035	6,035	6,035	5,765
3	5,225	5,855	5,855	5,855	5,585	6,395	6,035	6,665	6,665	6,665	6,215
4	4,685	5,045	5,045	5,045	4,775	5,135	4,775	5,225	5,225	5,225	4,955
5	3,795	3,965	3,965	3,965	3,695	3,965	3,785	4,055	4,055	4,055	3,875

Step 6a: Compute Undersaturated Segment Service Measures

Since the facility is globally undersaturated, the methodology proceeds to calculate service measures for each segment and each time period, starting with the first segment in Time Step 1. The computational details for each segment type are exactly as described in Chapters 11, 12, and 13. The weaving methodology in Chapter 13 checks whether the weaving short length L_S is less than or equal to the maximum weaving length $L_{W,MAX}$. It is assumed that, for any time interval, where L_S is longer than $L_{W,MAX}$, the weaving segment will operate as a basic freeway segment.

The key performance measures computed for each segment and each time step are the segment speed (Exhibit 10-31), density (Exhibit 10-32), and LOS (Exhibit 10-33).

AR0073491

Exhibit 10-31
Speed Matrix for Example Problem 1

Time Step	Speed (mi/h) by Segment										
	1	2	3	4	5	6	7	8	9	10	11
1	60.0	53.9	59.7	56.1	61.0	48.0	59.8	59.4	54.4	56.0	59.7
2	59.8	53.2	58.6	55.8	59.6	45.7	58.6	57.2	52.2	55.6	57.5
3	59.4	52.5	57.1	55.7	58.4	46.1	56.1	56.6	50.6	55.7	55.0

5	60.0	54.9	59.8	56.3	61.0	52.5	60.2	54.8	54.8	56.5	60.0

Exhibit 10-32
Density Matrix for Example Problem 1

Time Step	Density (veh/mi/ln) by Segment										
	1	2	3	4	5	6	7	8	9	10	11
1	25.0	30.7	27.7	29.4	26.0	27.2	27.1	34.2	34.2	31.7	28.2
2	27.6	34.5	31.0	32.8	29.7	31.3	31.3	38.5	38.5	36.2	33.4
3	29.3	37.7	44.2	35.0	31.0	34.0	35.6	44.9	43.9	40.5	47.7
4	26.2	31.3	28.2	30.0	26.5	25.8	29.5	37.5	37.5	31.1	27.9
5	21.0	24.1	22.1	23.6	20.5	18.9	21.3	24.7	24.7	23.9	21.5

Exhibit 10-33
LOS Matrix for Example Problem 1

Time Step	LOS by Segment										
	1	2	3	4	5	6	7	8	9	10	11
1	C	C	D	C	D	C	D	D	D	D	D
2	D	D	D	D	D	D	D	D	D	D	D
3	D	D	D	D	D	E	E	E	E	E	E
4	D	C	D	D	D	C	D	D	D	D	D
5	C	C	C	C	C	B	C	C	C	C	C

Step 7: Compute Facility Service Measures and Determine LOS

In the final analysis step, facilitywide performance and service measures are calculated for each time step. Examples of calculations are provided for the first time step only; summary results are shown for all five time steps.

First, the facility space-mean speed S is calculated for time interval t from the n individual segment flows $SF(i,t)$, segment lengths $L(i)$, and space-mean speeds in each segment and time period $U(i,t)$:

$$S(t) = \frac{\sum_{i=1}^{n} SF(i,t) \times L(i)}{\sum_{i=1}^{n} SF(i,t) \times \frac{L(i)}{U(i,t)}}$$

$$\sum_{i=1}^{n} SF(i,t) \times L(i) = 4{,}707 \times 5{,}280 + 4{,}970 \times 5{,}280 + 4{,}955 \times 2{,}280 + 4{,}955 \times 1{,}500 + 4{,}687 \times 5{,}280 + 5{,}225 \times 2{,}640 + 4{,}567 \times 5{,}280 + 5{,}315 \times 1{,}140 + 5{,}315 \times 360 + 5{,}315 \times 1{,}320 + 5{,}015 \times 5{,}280 = 154{,}836{,}000 \text{ veh-ft}$$

$$\sum_{i=1}^{n} SF(i,t) \times \frac{L(i)}{U(i,t)} = (4{,}707 \times 5{,}280/60.00) + (4{,}970 \times 1{,}500/53.40) + (4{,}955 \times 2{,}280/59.70) + (4{,}955 \times 1{,}500/60.10) + (4{,}687 \times 5{,}280/60.00) + (5{,}225 \times 2{,}640/48.00) + (4{,}567 \times 5{,}280/59.90) + (5{,}315 \times 1{,}140/53.10) + (5{,}315 \times 360/53.40) + (5{,}315 \times 1{,}320/56.00) + (5{,}015 \times 5{,}280/59.70) = 2{,}688{,}024 \text{ veh-ft/mi/h}$$

$$S(t) = \frac{154{,}836{,}000}{2{,}688{,}024} = 57.6 \text{ mi/h}$$

AR0073492

Second, the average facility density is calculated for Time Step 1 from the individual segment densities D, segment lengths L, and number of vehicles in each segment N:

$$D(t=1) = \frac{\sum_{i=1}^{11} D(i,1) \times L(i) \times N(i,1)}{\sum_{i=1}^{11} L(i) N(i,1)}$$

$$\sum_{i=1}^{11} D(i,1) \times L(i) \times N(i,1) = (25.0 \times 5,280 \times 3) + (30.7 \times 1,500 \times 3) + (27.7 \times 2,280 \times 3) + (29.4 \times 1,500 \times 3) + (26.0 \times 5,280 \times 3) + (27.2 \times 2,640 \times 4) + (27.1 \times 5,280 \times 3) + (33.2 \times 1,140 \times 3) + (35.2 \times 5,280 \times 3) + (31.7 \times 1,140 \times 3) + (28.2 \times 5,280 \times 3) = 2,687,957 \text{ (veh/mi/ln)(ln-ft)}$$

$$\sum_{i=1}^{11} L(i) N(i,1) = (5,280 \times 3) + (1,500 \times 3) + (2,280 \times 3) + (1,500 \times 3) + (5,280 \times 3) + (2,640 \times 4) + (5,280 \times 3) + (1,140 \times 3) + (5,280 \times 3) + (1,140 \times 3) + (5,280 \times 3) = 97,680 \text{ ln-ft}$$

$$D(t=1) = \frac{2,687,957}{97,680} = 27.5 \text{ veh/mi/ln}$$

These calculations are repeated for all five time steps. The overall space mean speed across all time intervals is calculated as follows:

$$S(p=5) = \frac{\sum_{p=1}^{5} \sum_{i=1}^{11} SF(i,p) L(i)}{\sum_{i=1}^{11} \sum_{p=1}^{5} SF(i,p) \frac{L(i)}{U(i,p)}}$$

The overall average density across all time intervals is calculated as follows:

$$D(p=5) = \frac{\sum_{p=1}^{5} \sum_{i=1}^{11} D(i,p) \times L(i) \times N(i,p)}{\sum_{p=1}^{5} \sum_{i=1}^{11} L(i) N(i,p)}$$

The resulting performance and service measures for Time Steps 1–5 and the facility totals are shown in Exhibit 10-34. The LOS for each time interval is determined directly from the average density for each time interval by using Exhibit 10-2. No LOS is defined for the average across all time intervals.

Exhibit 10-34
Facility Performance Measure Summary for Example Problem 1

Time Step	Performance Measures: Space Mean Speed (mi/h)	Performance Measures: Average Density (veh/mi/ln)	LOS
1	57.6	27.5	D
2	55.6	31.3	D
3	55.1	34.6	E
4	57.9	27.5	D
5	59.4	23.4	C
Total	**56.9**	**28.5**	—

AR0073493

Discussion

This facility turned out to be globally undersaturated. Consequently, the facility aggregated performance measures could be calculated directly from the individual segment performance measures. An assessment of the segment service measures across the time–space domain can begin to highlight areas of potential congestion. Visually, this process can be facilitated by plotting the v/c, s/c, speed, or density matrices in contour plots.

EXAMPLE PROBLEM 2: EVALUATION OF AN OVERSATURATED FACILITY

The Facility

The facility used in Example Problem 2 is identical to the one in Example Problem 1, which is shown in Exhibit 10-25 and Exhibit 10-26.

The Facts

In addition to the information in Exhibit 10-25 and Exhibit 10-26, the following characteristics of the freeway facility are known.

Heavy vehicles	=	5% trucks, 0% RVs (all movements);
Driver population	=	regular commuters;
FFS		60 mi/h (all mainline segments);
Ramp FFS		40 mi/h (all ramps);
Acceleration lane length	=	500 ft (all ramps);
Deceleration lane length		500 ft (all ramps);
$c_{i,m}$	=	190 pc/min/ln;
$c_{i,o}$		2,300 pc/h/ln (for LOS = 60 mi/h);
L_i		1,640 ft (for Weaving Segment 6);
FRO		1.0 ramp/mi;
Terrain	=	level;
Analysis duration		2 h; and (divided into five 15-min time steps); and
Demand adjustment	=	11% increase in demand volumes across all segments and time steps compared with Example Problem 1

Comments

The facility and all geometric inputs are identical to Example Problem 1. The same general comments apply. The results of Example Problem 1 suggested a globally undersaturated facility, but some segments were close to their capacity (v/c ratio approaching 1.0). In the present example, a facilitywide demand increase of 11% is applied to all segments and all time periods. Consequently, it is expected that parts of the facility may become oversaturated and that queues may form on the facility.

AR0073494

Step 1: Input Data

The freeway traffic demand inputs for all 11 segments and five analysis intervals are shown in Exhibit 10-35.

Time Step (15 min)	Entering Flow Rate (veh/h)	Ramp Flow Rates by Time Period (veh/h)						Exiting Flow Rate (veh/h)
		ONR1	ONR2[a]	ONR3	OFR1	OFR2	OFR3	
1	5,001	500	599 (56)	500	600	400	300	5,000
2	5,977	592	799 (111)	559	400	400	300	6,392
3	5,800	699	999 (107)	659	300	400	500	6,699
4	5,200	400	400 (90)	501	400	400	300	5,501
5	4,201	200	300 (56)	300	300	200	200	4,301

[a] Numbers in parentheses indicate ONR 2 to OFR 2 demand flows going to Freeway Segment 6.

Exhibit 10-35
Demand Inputs for Example Problem 2

The values in Exhibit 10-35 represent the adjusted demand flows on the facility as determined from field observations or demand projections. The actual volume served in each segment will be determined during application of the methodology and is expected to be less downstream of a congested segment. The demand flows are given for the extended time–space domain, consistent with this chapter's methodology. Peaking occurs in the third 15-min period. Since inputs are in the form of 15-min observations, no peak hour factor adjustment is necessary. Additional geometric and traffic-related inputs are as specified in Exhibit 10-23 and the facts section of the problem statement.

Step 2: Demand Adjustments

The traffic flows in Exhibit 10-35 have already been given in the form of actual demands and no further demand adjustments are necessary.

Step 3: Compute Segment Capacities

Since no changes to segment geometry were made, the segment capacities for basic and ramp segments are consistent with Example Problem 1 and Exhibit 10-25. Capacities for weaving segments are a function of weaving flow patterns, and the increased demand flows resulted in slight changes as shown in Exhibit 10-36.

Time Step	Capacities (veh/h) by Segment										
	1	2	3	4	5	6	7	8	9	10	11
1						8,753					
2						8,260					
3	6,737	6,732	6,732	6,732	6,732	8,304	6,732	6,732	6,732	6,732	6,732
4						8,382					
5						8,443					

Exhibit 10-36
Segment Capacities for Example Problem 2

Step 4: Adjust Segment Capacities

No capacity adjustments are made in this example.

Step 5: Compute Demand-to-Capacity Ratios

The demand-to-capacity ratios in Exhibit 10-37 are calculated from the demand flows in Exhibit 10-35 and from the segment capacities in Exhibit 10-36.

AR0073495

Exhibit 10-37
Segment Demand-to-Capacity Ratios for Example Problem 2

Time Step	Demand-to-Capacity Ratios by Segment										
	1	2	3	4	5	6	7	8	9	10	11
1	0.74	0.82	0.82	0.82	0.77	0.70	0.80	0.88	0.88	0.88	0.83
2	0.82	0.91	0.91	0.91	0.85	0.78	0.91	1.00	1.00	1.00	0.91
3	0.86	0.97	0.97	0.97	0.92	0.85	1.00	**1.10**	**1.10**	**1.10**	**1.02**
4	0.77	0.83	0.83	0.83	0.75	0.68	0.79	0.86	0.86	0.86	0.82
5	0.62	0.69	0.69	0.69	0.61	0.57	0.67	0.67	0.67	0.67	0.61

The completed cycle matrix in Exhibit 10-37 shows that segments 8–11 now have cycle ratios greater than 1.0 (bold values). Consequently, the facility is categorized as *oversaturated* and the analysis proceeds with computing the oversaturated service measures in Step 6b. Further, it is expected that queuing will occur on the facility upstream of the congested segments and that the volume served in each segment downstream of the congested segments will be less than the demand. This residual demand will be served in later time intervals, provided that upstream demand drops and queues are cleared to clear.

Step 6b: Compute Oversaturated Segment Service Measures

The oversaturated computations apply to any segment with a cycle ratio greater than 1.0 as well as any segments upstream of those segments that experience queuing as a result of the bottleneck. All remaining segments are analyzed by using the individual segment methodologies of Chapters 11, 12, and 13, as applicable, with the caveat that volumes served may differ from demand flows.

Similar to Example Problem 1, the methodology calculates performance measures for each segment and each time period, starting with the first segment in Time Step 1. The computations are repeated for all segments for Time Steps 1 and 2 without encountering a segment with cycle > 1.0. Once the methodology enters Time Period 3 and Segment 8, the oversaturated computational module is invoked.

As the first active bottleneck, the cycle ratio for Segment 8 will be exactly 1.0 and will process traffic at its capacity. Consequently, demand for all downstream segments will be metered by that bottleneck. The unsatisfied demand is stored in upstream segments, which causes queuing in Segment 7 and perhaps further upstream segments, depending on the level of excess demand. The rate of growth of the vehicle queue (wave speed) is estimated from shock wave theory, as discussed in detail in Chapter 25, Freeway Facilities: Supplemental. The performance measures (speed and density) of any segment with queuing are recomputed as discussed in Chapter 25, and the newly calculated values override the results from the segment-specific procedures.

Any unserviced demand is serviced in later time periods. As a result, volumes served in later time periods may be higher than the period demand flows. The resulting matrix of volumes served for Example Problem 2 is shown in Exhibit 10-38. The table emphasizes cells where volumes served are less than demand flows (in **bold**) and where volumes served are greater than demand flows (*italicized*).

AR0073496

Exhibit 10-38
Volume Served Matrix for Example Problem 2

Time Step	Volumes Served (veh/h) by Segment										
	1	2	3	4	5	6	7	8	9	10	11
1	5,000	5,500	5,500	5,500	5,200	5,600	5,400	5,000	5,000	5,000	5,600
2	5,500	6,099	6,099	6,099	5,700	6,400	6,099	6,699	6,699	6,699	6,099
3	5,800	6,499	6,499	6,499	**6,115**	**6,625**	**6,037**	**6,737**	**6,737**	**6,737**	**6,777**
4	5,200	5,500	5,600	5,500	*5,369*	*6,173*	*5,967*	*6,466*	*6,466*	*6,466*	*6,122*
5	4,200	4,401	4,401	4,401	4,131	4,401	4,201	4,501	4,501	4,501	4,401

As a result of the bottleneck activation in Segment 8 in Time Period 3, queues form in upstream Segments 7, 6, and 5. The queuing is associated with reduced speeds and increased densities in those segments. Details on how those measures are calculated for oversaturated segments are given in Chapter 25. The results in this chapter were obtained from the FREEVAL-2010 engine. The resulting performance measures computed for each segment and time interval are the speed (Exhibit 10-39), density (Exhibit 10-40), and LOS (Exhibit 10-41).

Exhibit 10-39

The LOS table for oversaturated facilities (Exhibit 10-41) distinguishes between the conventional density-based LOS and a segment demand-based LOS. The density-based stratification strictly depends on the prevailing average density on each segment. Segments downstream of the bottleneck, whose capacities are greater than or equal to the bottleneck capacity, operate at LOS F (or better), even though their v/c ratios were greater than 1.0. The demand-based LOS identifies those segments with demand-to-capacity ratios exceeding 1.0 as if they had been evaluated in isolation (i.e., using methodologies of Chapters 11,

AR0073497

12, and 13). By contrasting the two parts of the LOS Table, the analyst can develop an understanding of the governing driver of the bottleneck.

Step 7: Compute Facility Service Measures and Determine LOS

In the final analysis step, facilitywide performance and service measures are calculated for each time interval (Exhibit 10-42), consistent with Example Problem 1. Only summary results are shown in this case, since the computations have already been shown. The facility operates at LOS F in Time Period 3, since one or more individual segments have D/C ratios > 1.0, even though the average facility density is below the LOS F threshold.

Exhibit 10-42
Facility Performance Measure Summary for Example Problem 2

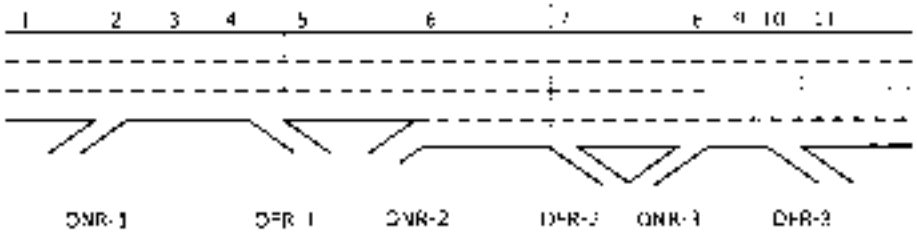
Time Interval	Performance Measure: Space Mean Speed (mi/h)	Performance Measure: Average Density (veh/mi/ln)	LOS
1	56.7	31.0	D
2	54.5	36.1	E
3	46.3	43.7	F
4	52.8	34.1	E
5	58.2	23.3	C
Total	**52.9**	**34.0**	—

EXAMPLE PROBLEM 3: CAPACITY IMPROVEMENTS TO AN OVERSATURATED FACILITY

The Facility

In this example, portions of the congested facility in Example Problem 2 are being improved in an attempt to alleviate the congestion resulting from the Segment 6 bottleneck. Exhibit 10-43 shows the upgraded facility geometry.

Exhibit 10-43
Freeway Facility in Example Problem 3



The modified geometry of the 6-mi directional freeway facility is reflected in Exhibit 10-44.

Exhibit 10-44
Geometry of Directional Freeway Facility in Example Problem 3

Segment No.	1	2	3	4	5	6	7	8	9	10	11
Segment type	B	ONR	B	OFR	B	B or W	B	ONR	R	OFR	B
Segment length (ft)	5,280	1,500	2,280	1,500	5,280	2,640	5,280	1,140	260	1,140	5,280
No. of lanes	3	3	3	3	3	4	4	4	4	4	4

Note: B = basic freeway segment; W = weaving segment; ONR = on-ramp (merge) segment; OFR = off-ramp (diverge) segment; R = ramp (only one lane); bold type indicates geometric changes from Example Problems 1 and 2.

AR0073498

The facility improvements consisted of adding a lane to Segments 7–11 to give the facility a continuous four-lane cross section starting in Segment 6. While the active bottleneck in Example Problem 2 was in Segment 8, the prior analysis showed that other segments (Segments 9–11) showed similar demand to capacity ratios greater than 1.0. Consequently, any capacity improvements that are limited to Segment 8 would have merely moved the spatial location of the bottleneck to either downstream rather than improving the overall facility. Segments 9–11 may also be referred to as "hidden" or "latent" bottlenecks because their predicted congestion is mitigated by the upstream metering of traffic.

The Facts

In addition to the information contained in Exhibit 10-43 and Exhibit 10-44, the following characteristics of the freeway facility are known.

Heavy vehicles	= 5% trucks, 0% RVs (all movements),
Driver population	= regular commuters,
FFS	= 60 mi/h (all mainline segments),
Ramp *FFS*	= 40 mi/h (all ramps),
Acceleration lane length	= 500 ft (all ramps),
Deceleration lane length	= 500 ft (all ramps),
D_{cr}	= 130 pc/mi/ln,
c_{ad}	= 2,300 pc/h/ln (for *FFS* = 60 mi/h),
L_s	= 1,640 ft (for Weaving Segment 6),
TRD	= 1.0 ramp/mi,
Terrain	= level,
Analysis duration	= 75 min (divided into five 15-min intervals), and
Demand adjustment	= 11% (all segments and all time intervals).

Comments

The traffic demand flow inputs are identical to those in Example Problem 2, which reflected an 11% increase in traffic applied to all segments and all time periods. In an attempt to solve the congestion effect found in the earlier example, the facility was widened in Segments 7 and 11. This change directly affects the capacities of those segments.

In a more subtle way, the proposed modifications also change some of the defining parameters of Weaving Segment 6 as well. With the added continuous lane downstream of the segment, the required number of lane changes from the ramp to the freeway is reduced from one to zero, following the guidelines in Chapter 12. These changes need to be considered when the undersaturated performance of that segment is evaluated. The weaving segment's capacity is unchanged relative to Example Problem 2, since, even with the proposed improvements, the number of weaving lanes remains two.

AR0073499

Step 1: Input Data

Traffic demand inputs for all 11 segments and five analysis intervals are coded in the same manner as in Example Problem 2 as shown in Exhibit 10-35. The values in Exhibit 10-35 represent the adjusted demand flows on the facility as determined from field observations or other sources. The actual volume served in each segment will be determined during the methodologies and is expected to be less downstream of a congested segment. Additional geometric and traffic-related inputs are as specified in Exhibit 10-44 and the facts section of the problem statement.

Step 2: Demand Adjustments

The traffic flows in Exhibit 10-35 have already been given in the form of actual demands and no further demand adjustments are necessary.

Step 3: Compute Segment Capacities

Segment capacities are determined by using the methodologies of Chapter 11 for basic freeway segments, Chapter 12 for weaving segments, and Chapter 13 for merge and diverge segments. The resulting capacities are shown in Exhibit 10-45. Since the capacity of a weaving segment depends on traffic patterns, it varies by time period. The remaining capacities are constant for all five time steps. The capacities for Segments 1–5 and for Segments 7–11 are the same, since the segments have the same basic cross section.

Exhibit 10-45
Segment Capacities for Example Problem 3

Time Step	Capacities (veh/h) by Segment										
	1	2	3	4	5	6	7	8	9	10	11
1						8,253					
2						8,700					
3	6,732	6,732	6,732	6,732	6,732	8,403	8,976	8,976	8,976	8,976	8,976
4						8,382					
5						8,418					

Step 4: Adjust Segment Capacities

No additional capacity adjustments are made in this example.

Step 5: Compute Demand-to-Capacity Ratios

The demand-to-capacity ratios are calculated from the demand flows in Exhibit 10-35 and segment capacities in Exhibit 10-45.

Exhibit 10-46
Segment Demand-to-Capacity Ratios for Example Problem 3

Time Step	Demand-to-Capacity Ratio by Segment										
	1	2	3	4	5	6	7	8	9	10	11
1	0.74	0.82	0.82	0.82	0.77	0.73	0.60	0.56	0.56	0.62	0.62
2	0.82	0.91	0.91	0.91	0.85	0.79	0.68	0.75	0.75	0.75	0.71
3	0.86	0.97	0.97	0.97	0.90	0.85	0.75	0.82	0.82	0.82	0.77
4	0.77	0.83	0.83	0.83	0.79	0.69	0.59	0.65	0.65	0.65	0.61
5	0.62	0.55	0.66	0.65	0.51	0.52	0.47	0.50	0.50	0.50	0.48

The demand-to-capacity ratio matrix for Example Problem 3 (Exhibit 10-46) shows that the capacity improvements successfully restored all the previously congested segments to $v/c < 1.00$. Therefore, it is expected that the facility will operate as originally understood and that all segment performance measures can

AR0073500

be directly computed by using the methodologies in Chapters 11, 12, and 13 in Step 6a.

Step 6a: Compute Undersaturated Segment Service Measures

Since the facility is globally undersaturated, the methodology proceeds to calculate performance and service measures for each segment and each time step, starting with the first segment in Time Interval 1. The computational details for each segment type are exactly as described in Chapters 11, 12, and 13. The weaving methodology in Chapter 13 checks whether the weaving short length L_S is less than or equal to the maximum weaving length L_{max}. It is assumed that, for any time interval where L_S is longer than L_{max}, the weaving segment will operate as a basic freeway segment.

The basic performance service measures computed for each segment and each time interval include the segment speed (Exhibit 10-47), density (Exhibit 10-48), and LOS (Exhibit 10-49).

Time Step	Speed (mi/h) by Segment										
	1	2	3	4	5	6	7	8	9	10	11

Exhibit 10-49
LOS Matrix for Example Problem 3

AR0073501

Step 7: Compute Facility Service Measures and Determine LOS

In the final analysis step, facilitywide performance and service measures are calculated for each time step (Exhibit 10-50), consistent with Example Problem 2. Only summary results are shown in this case, since the computations have already been shown. The improvement has been able to restore the facility LOS to the values experienced in the original progression scenario shown in Exhibit 10-34.

AR0073506

1. INTRODUCTION

Basic freeway segments are defined as those freeway segments that are outside the influence of merging, diverging, or weaving maneuvers. In general, this means that lane-changing activity is not significantly influenced by the presence of ramps and weaving segments. Lane-changing activity primarily reflects the normal desire of drivers to optimize their efficiency through lane-changing and passing maneuvers.

A complete discussion of influence areas is included in Chapter 10, Freeway Facilities, with additional discussion in Chapters 12, Freeway Weaving Segments, and 13, Freeway Merge and Diverge Segments. In general terms, the influence area of merge (on-ramp) segments extends for 1,500 ft downstream of the merge point, the influence area of diverge (off-ramp) segments extends for 1,500 ft upstream of the diverge point, and the influence area of weaving segments extends 500 ft upstream and downstream of the segment itself. This description is not to suggest that the influence of these segments cannot extend over a broader range, particularly under breakdown conditions. Under stable operations, however, these distances define the areas most affected by merge, diverge, and weaving movements. The impact of breakdown on any type of freeway segment on adjacent segments can be addressed by using the methodology of Chapter 10, Freeway Facilities.

Chapter 11, Basic Freeway Segments, provides a methodology for analyzing the capacity and level of service (LOS) of existing or planned basic freeway segments. The methodology can also be used for design applications, where the number of lanes needed to provide a target LOS for an existing or projected demand flow rate can be found.

Analysis segments must have uniform geometric and traffic conditions, including demand flow rate.

Such analyses are applied to basic freeway segments with uniform characteristics. Uniform segments must have the same geometric and traffic characteristics, including a constant demand flow rate.

BASE CONDITIONS

Base conditions exclude good weather and visibility and no incidents or accidents. These conditions are always assumed to exist.

The base conditions under which the full capacity of a basic freeway segment is achieved include good weather, good visibility, no incidents or accidents, no work zone activity, and no pavement deterioration serious enough to affect operations. This chapter's methodology assumes that these conditions exist. If any of these conditions do not exist, the speed, LOS, and capacity of the freeway segment can be expected to be worse than those predicted by this methodology.

Base conditions also include the following conditions, which can be adjusted as the methodology is applied to address situations in which these conditions do not exist:

AR0073507

Base conditions also include 0% heavy vehicles, a driver population composed of regular users of the roadway, and 12-ft lane widths and minimum 6-ft right-side clearances.

The methodology provides adjustments for situations when these conditions do not apply.

- No heavy vehicles (trucks, buses, recreational vehicles [RVs]) in the traffic stream,
- A driver population composed primarily of regular users who are familiar with the facility, and
- Minimum 12-ft lane widths and 6-ft right-side clearances.

FLOW CHARACTERISTICS UNDER BASE CONDITIONS

Traffic flow within basic freeway segments can be highly variable depending on the conditions constricting flow at upstream and downstream bottleneck locations. Such bottlenecks can be created by merging, diverging, or weaving traffic; lane drops; maintenance and construction activities; traffic accidents or incidents; objects in the roadway; or all of the foregoing. Bottlenecks can exist even when a lane is not fully blocked. Partial blockages will cause drivers to slow and divert their paths. In addition, the practice of rubbernecking near roadside incidents or accidents can cause additional bottlenecks.

Types of Flow

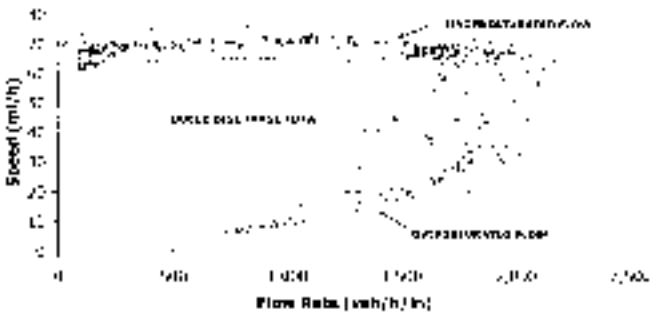
Chapter 3 describes in more detail the types of traffic flow on basic freeway segments.

As was discussed in more detail in Chapter 3, Applications, traffic flow within a basic freeway segment can be categorized as one of three general types: undersaturated, queue discharge, and oversaturated.

- *Undersaturated flow* represents conditions under which the traffic stream is unaffected by upstream or downstream bottlenecks.
- *Queue discharge flow* represents traffic flow that has just passed through a bottleneck and is accelerating back to drivers' desired speeds for the prevailing conditions. As long as another downstream bottleneck does not exist, queue discharge flow is relatively stable until the queue is fully discharged.
- *Oversaturated flow* represents the conditions within a queue that was backed up from a downstream bottleneck. These flow conditions do not reflect the prevailing conditions of the site itself but rather the consequences of a downstream problem. All oversaturated flow is considered to be congested.

An example of each of the three types of flow discussed is illustrated in Exhibit 11-1, using data from a freeway in California.

Exhibit 11-1
Three Types of Freeway Flow



Note: I-405, Los Angeles, Calif.
Source: California Department of Transportation, 2008.

AR0073508

The analysis methodology for basic freeway segments is based entirely on calibrations of the speed–flow relationships under base conditions with undersaturated flow. The methodology identifies cases in which failure has occurred but does not attempt to describe operating conditions when a segment has failed. The methodology of Chapter 10, Freeway Facilities, should be used for oversaturated conditions.

The basic freeway segment methodology is based on undersaturated flow conditions

Speed–Flow Curves for Base Conditions

A set of speed–flow curves for basic freeway segments operating under base conditions is shown in Exhibit 11-2. There are five curves, one for each of five levels of free-flow speed (FFS): 75 mi/h, 70 mi/h, 65 mi/h, 60 mi/h, and 55 mi/h. Technically speaking, the FFS is the speed at the y-intercept of each curve. In practical terms, there are two ranges in the shape of the curves:

- For each curve, a range of flows exists from 0 pc/h/ln to a breakpoint in which speed remains constant at the FFS. The ranges vary for each of the curves as follows:
  - FFS = 75 mi/h: 0–1,300 pc/h/ln;
  - FFS = 70 mi/h: 0–1,200 pc/h/ln;
  - FFS = 65 mi/h: 0–1,400 pc/h/ln;
  - FFS = 60 mi/h: 0–1,600 pc/h/ln; and
  - FFS = 55 mi/h: 0–1,800 pc/h/ln.
- At flow rates above the breakpoint of each curve, speeds decline at an increasing rate until capacity is reached.

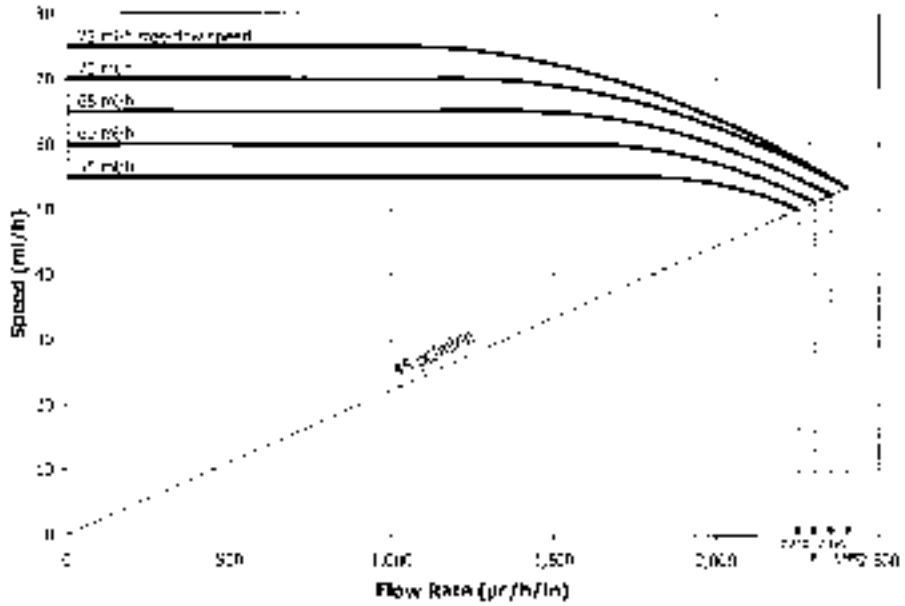


Exhibit 11-2
Speed–Flow Curves for Basic Freeway Segments Under Base Conditions

Exhibit 11-3 shows the equations that define each of the curves in Exhibit 11-2. Because estimating or measuring FFS is difficult, and there is considerable variation in observed and predicted values, no attempt should be made to

AR0073509

FFS should be rounded to the nearest 5 mi/h.

interpolate between the basic curves. FFS should be rounded to the nearest 5 mi/h as follows:

- ≥72.5 mi/h < 77.5 mi/h: use FFS = 75 mi/h,
- ≥67.5 mi/h < 72.5 mi/h: use FFS = 70 mi/h,
- ≥62.5 mi/h < 67.5 mi/h: use FFS = 65 mi/h,
- ≥57.5 mi/h < 62.5 mi/h: use FFS = 60 mi/h,
- ≥52.5 mi/h < 57.5 mi/h: use FFS = 55 mi/h.

Exhibit 11-3
Equations Describing Speed–Flow Curves in Exhibit 11-2 (Speeds in mi/h)

FFS (mi/h)	Breakpoint (pc/h/ln)	Flow Rate Range: 0 ≤ Breakpoint	Flow Rate Range: >Breakpoint ≤ Capacity
75	1,000	75	$75 - 0.00001107 (v_p - 1,000)^2$
70	1,200	70	$70 - 0.00001160 (v_p - 1,200)^2$
65	1,400	65	$65 - 0.00001419 (v_p - 1,400)^2$
60	1,600	60	$60 - 0.00001826 (v_p - 1,600)^2$
55	1,800	55	$55 - 0.00002469 (v_p - 1,800)^2$

Notes: FFS = free-flow speed; v_p = demand flow rate (pc/h/ln) under equivalent base conditions.
Maximum flow rate for the equations is capacity: 2,400 pc/h/ln for 70- and 75-mi/h FFS; 2,350 pc/h/ln for 65-mi/h FFS; 2,300 pc/h/ln for 60-mi/h FFS; and 2,250 pc/h/ln for 55-mi/h FFS.

The research leading to these curves (*1, 2*) found that several factors affect the FFS of a basic freeway segment, including the lane width, right-shoulder clearance, and ramp density. Ramp density is the average number of on-ramps plus off-ramps in a 3-mi range, 3 mi upstream and 3 mi downstream of the midpoint of the study segment. Many other factors are likely to influence FFS, horizontal and vertical alignment, posted speed limits, level of speed enforcement, lighting conditions, and weather. Although these factors may affect FFS, little information is available that would allow their quantification.

CAPACITY UNDER BASE CONDITIONS

The capacity of a basic freeway segment under base conditions varies with the FFS. For 70- and 75-mi/h FFS, the capacity is 2,400 pc/h/ln. For lower levels of FFS, capacity diminishes slightly. For 65-mi/h FFS, the capacity is 2,350 pc/h/ln; for 60-mi/h FFS, 2,300 pc/h/ln; and for 55-mi/h FFS, 2,250 pc/h/ln.

Base capacity values refer to the average flow rate across all lanes. Individual lanes could have stable flows in excess of these values.

Chapter 10, Freeway Facilities, contains information that would allow these values to be reduced to reflect long- and short-term construction and maintenance activities, adverse weather conditions, and accidents or incidents.

Since freeways usually do not operate under base conditions, observed capacity values will typically be lower than the base capacity values.

These values represent national norms. It should be remembered that capacity varies stochastically and that any given location could have a larger or smaller value. It should also be remembered that capacity refers to the *average* flow rate across all lanes. Thus, a three-lane basic freeway segment with a 70-mi/h FFS would have an expected base capacity of 3 × 2,400 = 7,200 pc/h. This flow would not be uniformly distributed across all lanes. Thus, one or two lanes could have stable case flows in excess of 2,400 pc/h/ln.

As shown in Exhibit 11-2, it is believed that basic freeway segments reach capacity at a density of approximately 45 passenger cars per mile per lane (pc/mi/ln), which may vary slightly from location to location. At this density,

AR0073510

vehicles are too closely spaced to dampen the impact of any perturbation in flow, such as a lane change or a vehicle entering the freeway, without causing a disruption that propagates upstream.

LOS FOR BASIC FREEWAY SEGMENTS

LOS for basic freeway segments is defined by density.

LOS on a basic freeway segment is defined by density. Although speed is a major concern of drivers as related to service quality, it would be difficult to describe LOS by using speed, since it remains constant up to flow rates of 1,000 to 1,800 pc/h/ln, depending on the FFS. Density describes the proximity to other vehicles and is related to the freedom to maneuver within the traffic stream. Unlike speed, however, density is sensitive to flow rates throughout the range of flows.

Exhibit 11-4 visually demonstrates the six LOS defined for basic freeway segments. LOS are defined to represent reasonable ranges in the three critical flow variables: speed, density, and flow rate.

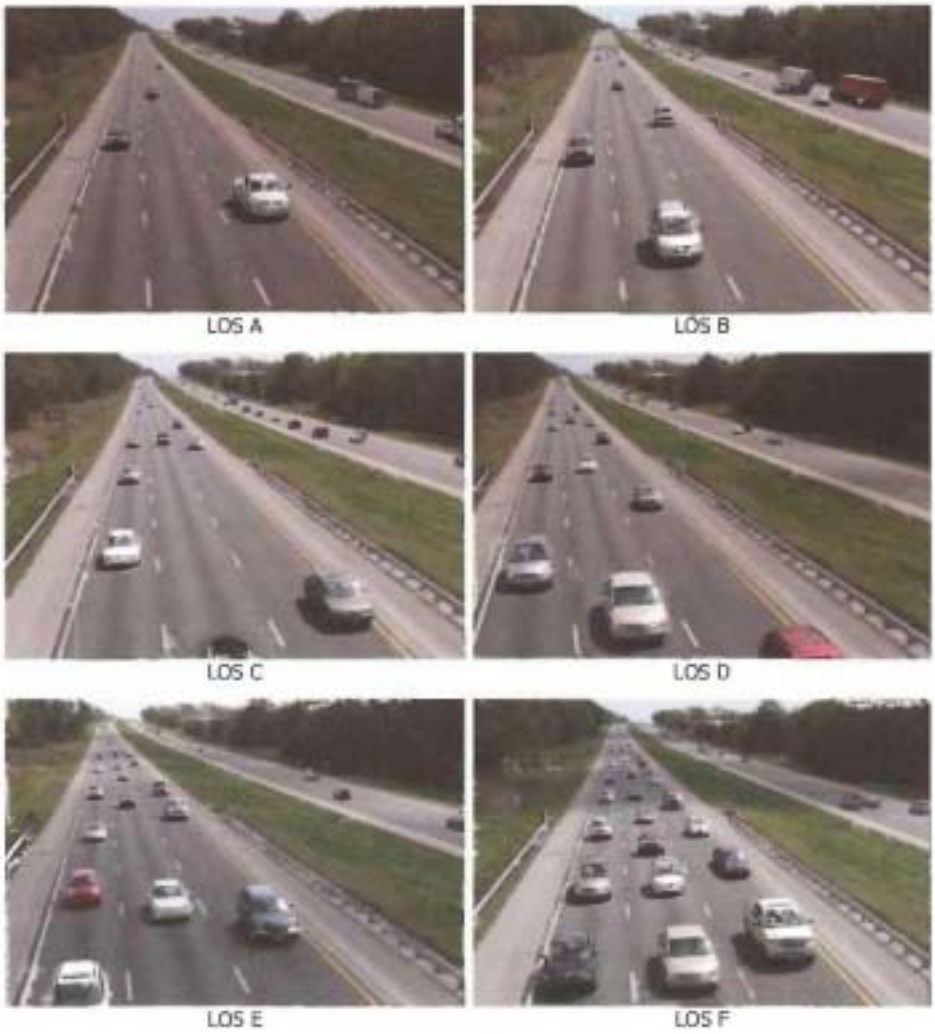

Exhibit 11-4
LOS Examples

AR0073511

Freeway LOS Described

LOS A describes free-flow operations. FFS prevails on the freeway, and vehicles are almost completely unimpeded in their ability to maneuver within the traffic stream. The effects of incidents or point breakdowns are easily absorbed.

LOS B represents reasonably free-flow operations, and FFS on the freeway is maintained. The ability to maneuver within the traffic stream is only slightly restricted, and the general level of physical and psychological comfort provided to drivers is still high. The effects of minor incidents and point breakdowns are still easily absorbed.

LOS C provides for flow with speeds near the FFS of the freeway. Freedom to maneuver within the traffic stream is noticeably restricted, and lane changes require more care and vigilance on the part of the driver. Minor incidents may still be absorbed, but the local deterioration in service quality will be significant. Queues may be expected to form behind any significant blockages.

LOS D is the level at which speeds begin to decline with increasing flows, with density increasing more quickly. Freedom to maneuver within the traffic stream is seriously limited and drivers experience reduced physical and psychological comfort levels. Even minor incidents can be expected to create queuing, because the traffic stream has little space to absorb disruptions.

LOS E describes operation at capacity. Operations on the freeway at this level are highly volatile because there are virtually no usable gaps within the traffic stream, leaving little room to maneuver within the traffic stream. Any disruption to the traffic stream, such as vehicles entering from a ramp or a vehicle changing lanes, can establish a disruption wave that propagates throughout the upstream traffic flow. At capacity, the traffic stream has no ability to dissipate even the most minor disruption, and any incident can be expected to produce a serious breakdown and substantial queuing. The physical and psychological comfort afforded to drivers is poor.

LOS F describes breakdown, or unstable flow. Such conditions exist within queues forming behind bottlenecks. Breakdowns occur for a number of reasons:

- Traffic incidents can temporarily reduce the capacity of a short segment, so that the number of vehicles arriving at a point is greater than the number of vehicles that can move through it.
- Points of recurring congestion, such as merge or weaving segments and lane drops, experience very high demand in which the number of vehicles arriving is greater than the number of vehicles that can be discharged.
- In analyses using forecast volumes, the projected flow rate can exceed the estimated capacity of a given location.

Breakdown (LOS F) occurs whenever the demand-to-capacity ratio exceeds 1.00.

In all cases, breakdown occurs when the ratio of existing demand to actual capacity, or of forecast demand to estimated capacity, exceeds 1.00. Operations immediately downstream of, or even at, such a point, however, are generally at or near LOS E, and downstream operations improve (assuming that there are no additional downstream bottlenecks) as discharging vehicles move away from the bottleneck.

AR0073512

LOS F operations within a queue are the result of a breakdown or bottleneck at a downstream point. In practical terms, the point of the breakdown has a *v/c* ratio greater than 1.00, and is also labeled LOS F, although actual operations at the breakdown point and immediately downstream may actually reflect LOS E conditions. Whenever queues due to a breakdown exist, they have the potential to extend upstream for considerable distances.

The effects of a breakdown can extend upstream for a considerable distance.

LOS Criteria

A basic freeway segment can be characterized by three performance measures: density in passenger cars per mile per lane (pc/mi/ln), space mean speed in miles per hour (mi/h), and the ratio of demand flow rate to capacity (*v/c*). Each of these measures is an indication of how well traffic is being accommodated by the basic freeway segment.

Because speed is constant through a broad range of flows and the *v/c* ratio is not directly discernible to road users (except at capacity), the service measure for basic freeway segments is density. Exhibit 11-5 shows the criteria.

Exhibit 11-5
LOS Criteria for Basic Freeway Segments

LOS	Density (pc/mi/ln)
A	≤11
B	>11–18
C	>18–26
D	>26–35
E	>35–45
F	Demand exceeds capacity >45

For all LOS, the density boundaries on basic freeway segments are the same as those for surface multilane highways, except at the LOS E/F boundary. Traffic characteristics are such that the maximum flow rates at any given LOS are lower on multilane highways than on similar basic freeway segments.

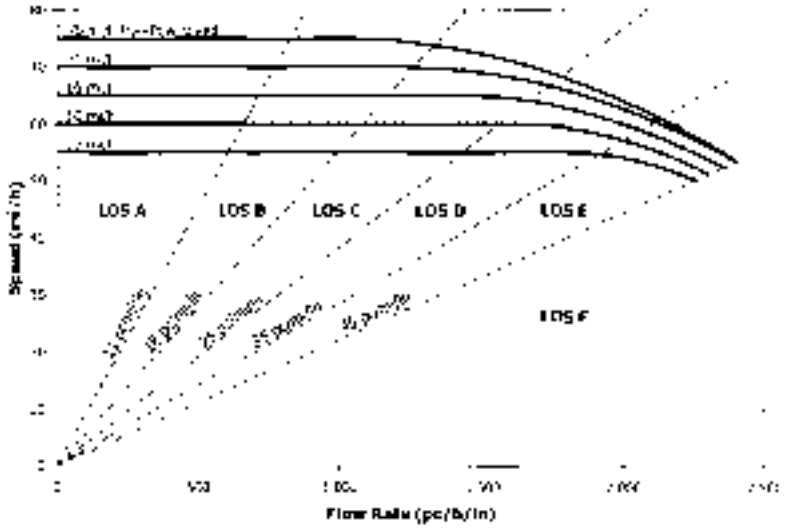
The specification of maximum densities for LOS A to D is based on the collective professional judgment of the members of the Transportation Research Board's Highway Capacity and Quality of Service Committee. The upper value shown for LOS E (45 pc/mi/ln) is the maximum density at which sustained flows at capacity are expected to occur. In effect, as indicated in the speed–flow curves of Exhibit 11-2, when a density of 45 pc/mi/ln is reached, flow is at capacity, and the *v/c* ratio is 1.00.

In the application of this chapter's methodology, however, LOS F is identified when demand exceeds capacity because the analytic methodology does not allow the determination of density when demand exceeds capacity. Although the density will be greater than 45 pc/mi/ln, the methodology of Chapter 10, Freeway Facilities, must be applied to determine a more precise density for such cases.

Exhibit 11-6 illustrates the defined LOS on the base speed–flow curves. On a speed–flow plot, density is a line of constant slope beginning at the origin. The LOS boundaries were defined to produce reasonable ranges within each LOS on these speed–flow relationships.

AR0073513

Exhibit 11-6
LOS for Basic Freeway Segments



REQUIRED INPUT DATA

The analysis of a basic freeway segment requires details concerning the geometric characteristics of the segment and the demand characteristics of the users of the segment. This section presents the required input data for the basic freeway segment methodology; specifics about individual parameters are given in the Methodology section.

Freeway Data

The following information on the segment's geometric features is needed to conduct an analysis (typical ranges for these parameters are shown):

1. FFS: 55 to 75 mi/h;
2. Number of mainline freeway lanes (one direction): at least two;
3. Lane width: 10 ft to 12 ft or more;
4. Right-side lateral clearance: 0 ft to more than 6 ft;
5. Total ramp density: 0 to 6 ramps/mi; and
6. Terrain: level, rolling, or mountainous; or specific length and percent grade.

Demand Data

The following information on the segment's users is required:

1. Demand during the analysis hour or daily demand and *K* and *D* factors;
2. Heavy-vehicle presence (proportion of trucks, buses, and RVs): 0 to 100% on general terrain, or 0 to 25% or more for specific grades;
3. Peak-hour factor (PHF): up to 1.00; and
4. Driver population factor: 0.85 to 1.00.

Length of Analysis Period

The analysis period for any freeway analysis is generally the peak 15-min period within the peak hour. Any 15-min period can be analyzed, however.

AR0073514

2. METHODOLOGY

This chapter's methodology can be used to analyze the capacity, LOS, lane requirements, and effects of design features on the performance of basic freeway segments. The methodology is based on the results of an NCHRP study (1), which has been partially updated (2). A number of significant publications were also used in the development of the methodology (3–12).

LIMITATIONS OF METHODOLOGY

This chapter's methodology does not apply to or take into account (without modification by the analyst) the following:

- Special lanes reserved for a single vehicle type, such as high-occupancy-vehicle (HOV) lanes, truck lanes, and climbing lanes;
- Lane control (by restricted lane changing);
- Extended bridge and tunnel segments;
- Segments near a toll plaza;
- Facilities with FFS less than 55 mi/h or more than 75 mi/h;
- The influence of downstream queuing on a segment;
- Posted speed limit and enforcement practices;
- Presence of intelligent transportation systems (ITS) related to vehicle or driver guidance;
- Capacity enhancing effects of ramp metering;
- Operational effects of oversaturated conditions; and
- Operational effects of construction operations.

In most of the cases just cited, the analyst would have to utilize alternative tools or draw on other research information and develop special-purpose modifications of this methodology to incorporate the effects of any of the cited conditions. Operational effects of oversaturated conditions, incidents, work zones, and weather and lighting conditions can be evaluated with the methodology of Chapter 10, Freeway Facilities. Operational effects of active traffic management measures are discussed in Chapter 35.

Active traffic management measures for freeways discussed in Chapter 35 consist of:

- *Dynamic shoulder running,*
- *Congestion pricing,*
- *Traveler information systems,*
- *Dynamic lane and shoulder management,*
- *Speed harmonization,*
- *Incident management, and*
- *Work zone traffic management.*

OVERVIEW OF METHODOLOGY

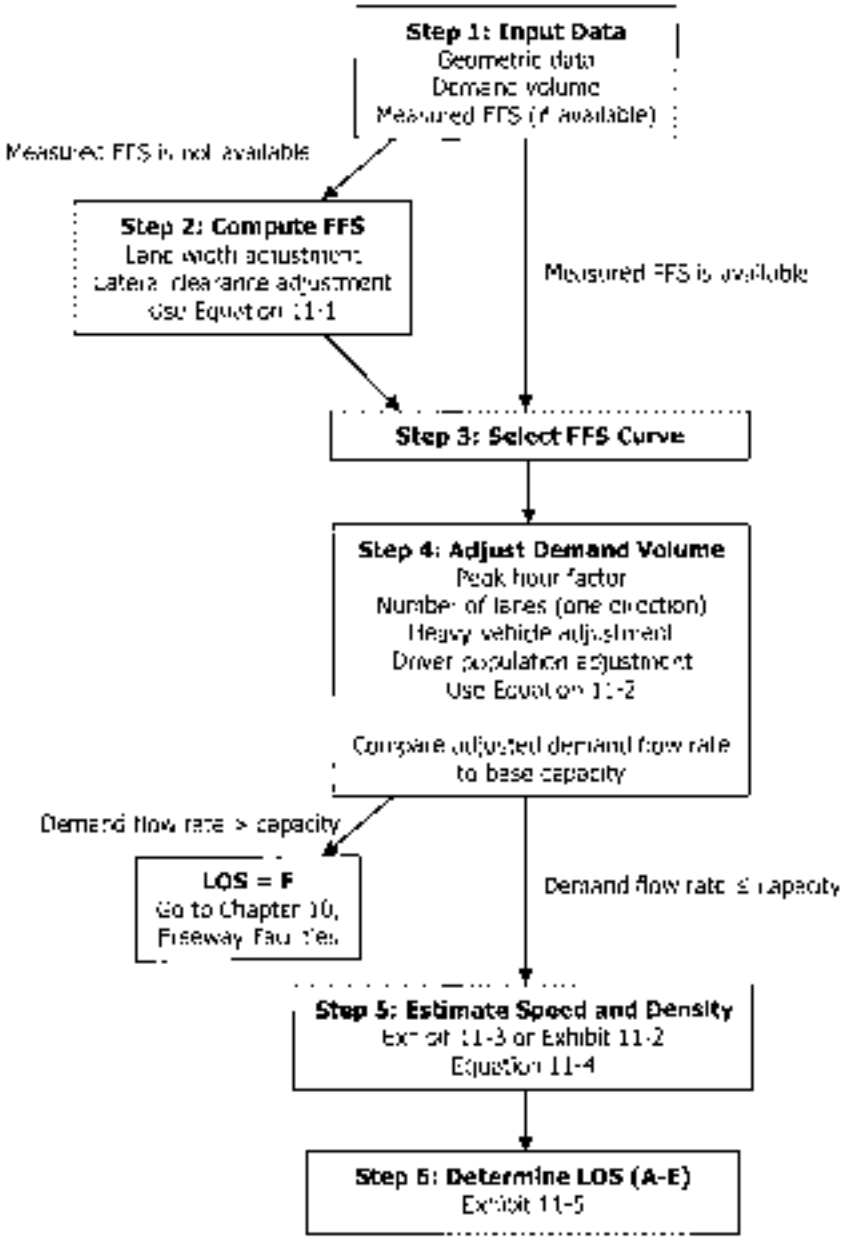
The methodology of this chapter is for the analysis of basic freeway segments. A method for analysis of extended lengths of freeway composed of a concatenation of basic freeway segments, weaving segments, and merge or diverge segments is found in Chapter 10, Freeway Facilities.

Exhibit 11-9 illustrates the basic methodology used in operational analysis. The methodology can also be directly applied to determine the number of lanes required to provide a target LOS for a given demand volume.

AR0073515

Exhibit 11-7
Overview of Operational Analysis Methodology for Base Freeway Segments

Exhibit 11-7 illustrates the methodology for operational analysis. Other types of analysis are described in the Applications section.



COMPUTATIONAL STEPS

Step 1: Input Data

For a typical operational analysis, as noted previously, the analyst would have to specify (with either site-specific or default values) demand volume, number and width of lanes, right-side lateral clearance, total ramp density, percent of heavy vehicles (trucks, buses, and RVs), PHF, terrain, and the driver population factor.

Step 2: Compute FFS

FFS can be determined directly from field measurements or can be estimated as described below.

AR0073516

Field Measurement of FFS

FFS is the mean speed of passenger cars measured during periods of low to moderate flow (up to 1,000 pc/h/ln). For a specific freeway segment, average speeds are virtually constant at this range of flow rates. If the FFS can be field measured, this is the preferable way to make the determination. If the FFS is measured directly, no adjustments are applied to the measured value.

FFS is the mean speed of passenger cars during periods of low to moderate flow.

The speed study should be conducted at a location that is representative of the segment at a time when flow rates are less than 1,000 pc/h/ln. The speed study should measure the speeds of all passenger cars or use a systematic sample (e.g., every tenth car in each lane). A sample of at least 100 passenger-car speeds should be obtained. Any speed measurement technique that has been found acceptable for other types of traffic engineering applications may be used. Further guidance on the conduct of speed studies is provided in standard traffic engineering publications, such as the Institute of Transportation Engineers *Manual of Traffic Engineering Studies* (*11*).

Estimating FFS

It is not possible to make field measurements for future conditions, and field measurement may not be possible or practical in all existing cases. In such cases, the segment's FFS may be estimated by using Equation 11-1, which is based on the physical characteristics of the segment under study.

$$FFS = 75.4 \quad f_{LW} \quad f_{LC} \quad 3.22 TRD^{0.84} \qquad \text{Equation 11-1}$$

where

FFS = FFS of basic freeway segment (mi/h),

f_{LW} = adjustment for lane width (mi/h),

f_{LC} = adjustment for right-side lateral clearance (mi/h), and

TRD = total ramp density (ramps/mi).

Base FFS

This methodology covers basic freeway segments with FFSs ranging from 55 mi/h to 75 mi/h. Thus, the predictive algorithm must start with a base speed of 75 mi/h or higher. A value of 75.4 mi/h was chosen, since it resulted in the most accurate predictions versus data collected in 2008.

Adjustment for Lane Width

The base condition for lane width is 12 ft or greater. When the average lane width across all lanes is less than 12 ft, the FFS is negatively affected. Adjustments to reflect the effect of narrower average lane widths are shown in Exhibit 11-8.

Average Lane Width (ft)	Reduction in FFS, f_{LW} (mi/h)
≥12	0.0
11–12	1.9
<11–11	9.6

Exhibit 11-8
Adjustment to FFS for Average Lane Width

AR0073517

Adjustment for Lateral Clearance

The base condition for right-side lateral clearance is 6 ft or greater. The lateral clearance is measured from the right edge of the travel lane to the nearest lateral obstruction. Care must be taken to identify a "lateral obstruction." Some obstructions may be continuous, such as retaining walls, concrete barriers, guardrails, or barrier curbs. Others may be periodic, such as light supports or bridge abutments. In some cases, drivers may become accustomed to certain types of obstructions, often making them influential on traffic negligible.

Exhibit 11-9 shows the adjustments to the base FFS due to the existence of obstructions closer than 6 ft to the right travel lane edge. Median clearances of 2 ft or more generally have little impact on traffic. No adjustments are available to reflect the presence of left-side lateral obstructions closer than 2 ft to the left travel lane edge. Such situations are, however, quite rare on modern freeways, except in constrained work zones.

Exhibit 11-9
Adjustment to FFS for Right-Side Lateral Clearance, f_{LC} (mi/h)

Right-Side Lateral Clearance (ft)	Lanes in One Direction			
	2	3	4	≥ 5
≥ 6	0.0	0.0	0.0	0.0
5	0.6	0.4	0.2	0.1
4	1.2	0.8	0.4	0.2
3	1.8	1.2	0.6	0.3
2	2.4	1.6	0.8	0.4
1	3.0	2.0	1.0	0.5
0	3.6	2.4	1.2	0.6

The impact of a right-side lateral clearance restriction depends on both the distance to the obstruction and the number of lanes in one direction on the basic freeway segment. A lateral clearance restriction causes vehicles in the right lane to move somewhat to the left. This movement, in turn, affects vehicles in the next lane. As the number of lanes increases, the overall effect on freeway operations decreases.

Total Ramp Density

Equation 11-1 includes a term that accounts for the impact of total ramp density on FFS. Total ramp density is defined as the number of ramps (on and off, one direction) located between 3 mi upstream and 3 mi downstream of the midpoint of the basic freeway segment under study, divided by 6 mi. The total ramp density has been found to be a measure of the impact of merging and diverging vehicles on FFS.

Step 3: Select FFS Curve

As noted previously, once the FFS of the basic freeway segment is determined, one of the five base speed–flow curves (Exhibit 11-2) is selected for use in the analysis. Interpolation between curves is not recommended. Criteria for selecting an appropriate curve were given in the text following Exhibit 11-2.

Step 4: Adjust Demand Volume

Since the basis speed–flow curves of Exhibit 11-2 are based on flow rates in equivalent passenger cars per hour, with the driver population dominated by

AR0073518

regular users of the basic freeway segment, demand volumes expressed as vehicles per hour under prevailing conditions must be converted to this basis. Equation 11-2 is used for this adjustment:

$$v_p = \frac{V}{PHF \times N \times f_{HV} \times f_p} \quad \text{Equation 11-2}$$

where

v_p = demand flow rate under equivalent base conditions (pc/h/ln),
V = demand volume under prevailing conditions (veh/h),
PHF = peak hour factor,
N = number of lanes in analysis direction,
f_{HV} = adjustment factor for presence of heavy vehicles in traffic stream, and
f_p = adjustment factor for unfamiliar driver populations.

Peak Hour Factor

The PHF represents the variation in traffic flow within an hour. Observations of traffic flow consistently indicate that the flow rates found in the peak 15 min within an hour are not sustained throughout the entire hour. The application of the PHF in Equation 11-2 accounts for this phenomenon.

On freeways, typical PHFs range from 0.85 to 0.98 (15). Lower values within that range are typical of lower volume conditions. Higher values within that range are typical of urban and suburban peak hour conditions. Field data should be used if possible to develop PHFs that represent local conditions.

Adjustment for Heavy Vehicles

A heavy vehicle is defined as any vehicle with more than four wheels on the ground during normal operation. Such vehicles are generally categorized as trucks, buses, or RVs. Trucks cover a wide variety of vehicles, from single-unit trucks with double rear tires to triple-unit tractor–trailer combinations. Small panel or pickup trucks with only four wheels are, however, classified as passenger cars. Buses include intercity buses, public transit buses, and school buses. Because buses are in many ways similar to single-unit trucks, both types of vehicles are considered in one category. RVs include a wide variety of vehicles from self-contained motor homes to cars and small trucks with trailers (for boats, all-terrain vehicles, or other conveyances). It should be noted that most sport-utility vehicles have only four wheels and are thus categorized as passenger cars. The heavy vehicle adjustment factor f_{HV} is computed as follows:

$$f_{HV} = \frac{1}{1 + P_T(E_T - 1) + P_R(E_R - 1)} \quad \text{Equation 11-3}$$

AR0073519

where

f_{HV} = heavy-vehicle adjustment factor,

P_T = proportion of trucks and buses in traffic stream,

P_R = proportion of RVs in traffic stream,

E_T = passenger-car equivalent (PCE) of one truck or bus in traffic stream, and

E_R = PCE of one RV in traffic stream.

The adjustment factor is found in a two-step process. First, the PCE for each truck or bus and RV is found for the prevailing conditions under study. These equivalency values represent the number of passenger cars that would use the same amount of freeway capacity as one truck or bus or RV under the prevailing conditions. Second, Equation 11-3 is used to convert the PCE values to the adjustment factor.

In many cases, trucks will be the only heavy vehicle type present in the traffic stream. In others, the percentage of RVs will be small in comparison with trucks and buses. If the ratio of trucks and buses to RVs is 5:1 or greater, all heavy vehicles may be (but do not have to be) considered to be trucks.

The effect of heavy vehicles on traffic flow depends on terrain and grade conditions as well as traffic composition. PCEs can be selected for one of three conditions:

- Extended freeway segments in general terrain,
- Specific upgrades, or
- Specific downgrades.

Each of these conditions is more precisely defined and discussed next.

Equivalents for General Terrain Segments

General terrain refers to extended lengths of freeway containing a number of upgrades and downgrades where no one grade is long enough or steep enough to have a significant impact on the operation of the overall segment. As a guideline for this determination, extended segment analysis can be applied where grades are ≤2% and ≤0.25 mi long, or where grades between 2% and 3% are ≤0.50 mi long. For this determination, each upgrade and downgrade is considered to be a single grade, even if the grade is not uniform. The total length of the upgrade or downgrade is used with the steepest grade it contains. There are three categories of general terrain:

- *Level terrain*. Any combination of grades and horizontal or vertical alignment that permits heavy vehicles to maintain the same speed as passenger cars. This type of terrain typically contains short grades of no more than 2%.
- *Rolling terrain*. Any combination of grades and horizontal or vertical alignment that causes heavy vehicles to reduce their speed substantially below those of passenger cars but that does not cause heavy vehicles to operate at crawl speeds for any significant length

AR0073520

of time or at frequent intervals. *Crawl speed* is the maximum sustained speed that trucks can maintain on an extended upgrade of a given percent. If the grade is long enough, trucks will be forced to decelerate to the crawl speed, which they can maintain for extended distances. Appendix A contains truck-performance curves illustrating crawl speed and length of grade.

- *Mountainous terrain*: Any combination of grades and horizontal and vertical alignment that causes heavy vehicles to operate at crawl speed for significant distances or at frequent intervals.

The mountainous terrain category is only used, because individual grades will typically be longer, steeper, or both, than the criteria for general terrain analysis.

Mountainous terrain is relatively rare. Generally, it segments severe enough to cause the type of operation described for mountainous terrain, individual grades will be longer or steeper, or both, than the criteria for general terrain analysis.

Exhibit 11-10 shows PCEs for trucks and buses and RVs in general terrain segments.

Exhibit 11-10
PCEs for Heavy Vehicles in General Terrain Segments

Vehicle	PCE by Type of Terrain		
	Level	Rolling	Mountainous
Trucks and buses, E_T	1.5	2.5	4.5
RVs, E_R	1.2	2.0	4.0

Equivalents for Specific Upgrades

Any freeway grade between 2% and 3% and longer than 0.5 mi or 3% or greater and longer than 0.25 mi should be considered a separate segment. The analysis of such segments must consider the upgrade conditions and the downgrade conditions separately, as well as whether the grade is a single, isolated grade of constant percentage or part of a series forming a composite grade. The analysis of composite grades is discussed in Appendix A.

Several studies have shown that freeway truck populations have an average weight-to-horsepower ratio between 125 and 150 lb/hp. This methodology adopts PCEs that are calibrated for a mix of trucks and buses in this range. RVs vary considerably in both type and characteristics and include everything from cars with trailers to self-contained mobile campers. In addition to the variability of vehicle characteristics, RV drivers are typically not professionals, and their degree of skill in handling such vehicles also varies widely. Typical RV weight-to-horsepower ratios range from 30 to 60 lb/hp.

Exhibit 11-11 and Exhibit 11-12 give values of E_T for trucks and buses and E_R for RVs, respectively. These factors vary with the percent of grade, length of grade, and the proportion of heavy vehicles in the traffic stream. Maximum values occur when there are only a few heavy vehicles in the traffic stream. The equivalents decrease as the number of heavy vehicles increases because these vehicles tend to form platoons. Because heavy vehicles have more uniform operating characteristics, fewer large gaps are created in the traffic stream when they platoon, and the impact of a single heavy vehicle in a platoon is less severe than that of a single heavy vehicle in a stream of primarily passenger cars. The aggregate impact of heavy vehicles on the traffic stream, however, increases as numbers and percentages of heavy vehicles increase.

AR0073521

The grade length should include 25% of the length of the vertical curves at the start and end of the grade.

With two consecutive upgrades, 50% of the length of the vertical curve joining them should be included.

The point of interest is usually the point where heavy vehicles would have the greatest impact on operations: the top of a grade, the top of the steepest grade in a series, or a ramp junction, for example.

The length of the grade is generally taken from a highway profile. It typically includes the straight portion of the grade plus some portion of the vertical curves at the beginning and end of the grade. It is recommended that 25% of the length of the vertical curves at both ends of the grade be included in the length. Where two consecutive upgrades are present, 50% of the length of the vertical curve joining them is included in the length of each grade.

In the analysis of upgrades, the point of interest is generally at the end of the grade, where heavy vehicles would have the maximum effect on operations. However, if a ramp junction is being analyzed, for example, the length of the grade to the merge or diverge point would be used.

On composite grades, the relative steepness of segments is important. If a 3% upgrade is followed by a 2% upgrade, for example, the maximum speed of heavy vehicles is most likely at the end of the 3% segment. Heavy vehicles would be expected to accelerate after entering the 2% segment.

Exhibit 11-11
PCEs for Trucks and Buses (E_T) on Upgrades

Upgrade (%)	Length (mi)	Proportion of Trucks and Buses								
		2%	4%	5%	6%	8%	10%	15%	20%	≥25%

Note: Interpolation for percentages of RVs is recommended to the nearest 0.1.

Exhibit 11-12
PCEs for RVs (E_R) on Upgrades

Equivalents for Specific Downgrades

Knowledge of specific impacts of heavy vehicles on operating conditions on downgrades is limited. In general, if the downgrade is not severe enough to cause trucks to shift into a lower gear (to engage engine braking), heavy vehicles may be treated as if they were on level terrain segments. Where a downgrade is severe, trucks must often use low gears to avoid gaining too much speed and running out of control. In such cases, their effect on operating conditions is more significant than on level terrain. Exhibit 11-13 gives values of E_T for this situation.

Downgrade (%)	Length of Grade (mi)	Proportion of Trucks and Buses 5%	10%	15%	≥20%
<4	All	1.5	1.5	1.5	1.5
4–5	≤4	1.5	1.5	1.5	1.5
	>4	2.0	2.0	2.0	1.5
>5–6	≤4	1.5	1.5	1.5	1.5
	>4	5.5	4.0	4.0	3.0
>6	≤4	1.5	1.5	1.5	1.5
	>4	7.5	6.0	5.5	4.5

Exhibit 11-13
PCEs for Trucks and Buses (E_T) on Specific Downgrades

On downgrades, RVs are always treated as if they were on level terrain; E_R is therefore always 1.2 on downgrades regardless of the length or severity of the downgrade or the percentage of RVs in the traffic stream.

E_R is always 1.2 on downgrades

Equivalents for Composite Grades

The vertical alignment of most freeways results in a continuous series of grades. It is often necessary to determine the effect of a series of grades in succession. The most straightforward technique is to compute the average grade from the beginning of the composite grade to the point of interest. The average grade is defined as the total rise from the beginning of the composite grade to the point in question divided by the length of the grade (to the point of interest).

The average grade can be used when all component grades are <4% or the total length of the grades is <4,000 ft

The average-grade technique is an acceptable approach for grades in which all subsections are less than 4% or the total length of the grade is less than 4,000 ft. For more severe composite grades, a detailed technique is presented in Appendix A. This technique uses vehicle performance curves and equivalent speeds to determine the equivalent sample grade for analysis.

Appendix A provides a method for addressing more severe composite grades

AR0073523

Adjustment for Driver Population

The base traffic stream characteristics for basic freeway segments are representative of traffic streams composed primarily of commuters, or drivers who are familiar with the facility. It is generally accepted that traffic streams with different characteristics (e.g., recreational drivers) use freeways less efficiently. Although data are sparse and reported results vary substantially, significantly lower capacities have been reported on weekends, particularly in recreational areas. It may generally be assumed that the reduction in capacity (LOS E) extends to service flow rates and service volumes for other LOS as well.

An f$_p$ value of 1.00 should generally be used, unless it is known that drivers who are regular users of the freeway.

The adjustment factor f_p is used to reflect the effect of driver population. The values of f_p range from 0.85 to 1.00 in most cases, although lower values have been observed in isolated cases. In general, the analyst should use a value of 1.00, which reflects commuters or otherwise accustomed drivers, unless there is sufficient evidence that a lower value should be used. Where greater accuracy is needed, comparative field studies of commuter and recreational traffic flows and speeds are recommended.

Does LOS F Exist?

At this point, the demand volume has been converted to a demand flow rate in passenger cars per hour per lane under equivalent base conditions. This demand rate must be compared with the base capacity of the basic freeway segment (2,400 pc/h/ln for FFS = 75 mi/h and 70 mi/h; 2,350 pc/h/ln for FFS = 65 mi/h; 2,300 pc/h/ln for FFS = 60 mi/h; 2,250 pc/h/ln for FFS = 55 mi/h).

If the demand exceeds capacity, the LOS is F, and a breakdown has been identified. To analyze the impacts of such a breakdown, the methodology of Chapter 10, Freeway Facilities, must be used. No further analysis using the methodology of the current chapter is possible.

If the demand is less than or equal to capacity, the analysis continues to Step 5.

Step 5: Estimate Speed and Density

At this point in the methodology, the following have been determined: (a) the FFS and appropriate LOS curve for use in the analysis, and (b) the demand flow rate expressed in passenger cars per hour per lane under equivalent base conditions. With this information, the estimated speed and density of the traffic stream may be determined.

With the equations specified in Exhibit 11-3, the expected mean speed of the traffic stream can be computed. A graphical solution with Exhibit 11-2 can also be performed.

With the estimated speed determined, Equation 11-4 is used to estimate the density of the traffic stream:

AR0073524

$$D = \frac{v_p}{S}$$

Equation 11-4

where

D = density (pc/mi/ln),

v_p = demand flow rate (pc/h/ln), and

S = mean speed of traffic stream under base conditions (mi/h).

As has been noted, Equation 11-4 is only used when the v/c is less than or equal to 1.00. All cases in which this ratio is greater than 1.00 are LOS F. In these cases, the speed S will be outside the range of Exhibit 11-3 and Exhibit 11-4, and no speed can be estimated.

Where LOS F exists, the analyst is urged to consult Chapter 10, Freeway Facilities, which addresses an analysis of the time and spatial impacts of a breakdown, including its effects on upstream and downstream segments.

Step 6: Determine LOS

Exhibit 11-3 is entered with the density obtained from Equation 11-4 to determine the expected prevailing LOS.

SENSITIVITY OF RESULTS

The freeway LOS is most sensitive to the total ramp density.

The FFS of basic freeway segments is most sensitive to the total ramp density. Exhibit 11-14 illustrates the resulting FFS when total ramp density varies from 0 ramps/mi to 6 ramps/mi. Standard lane widths and right-side clearances are assumed. A freeway with 0 ramps/mi represents a case in which there are no ramps within 3 mi on either side of the study location. This situation occurs primarily in rural areas, where interchanges may be 10 or more miles apart. In rare cases, ramp densities in excess of 6 ramps/mi may exist, particularly in dense urban areas.

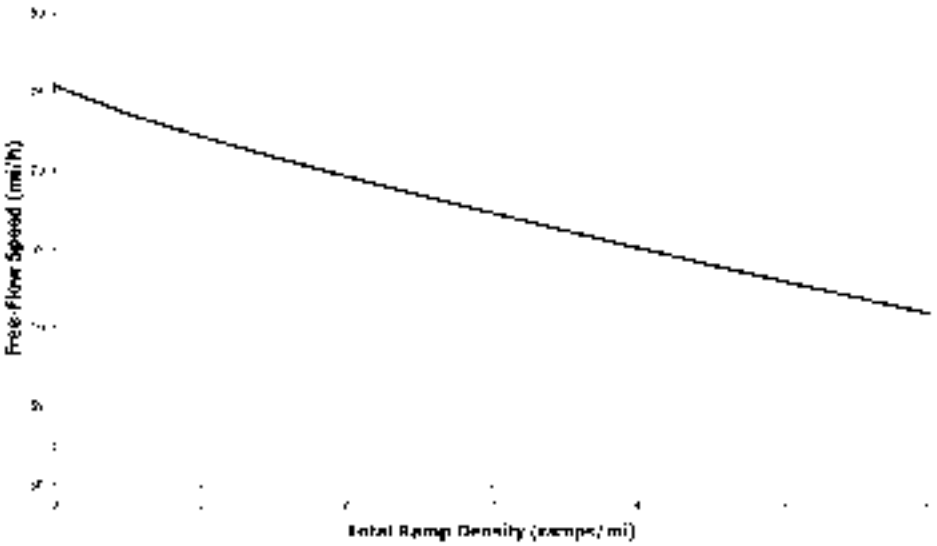

Exhibit 11-14
Sensitivity of FFS to Total Ramp Density

AR0073525

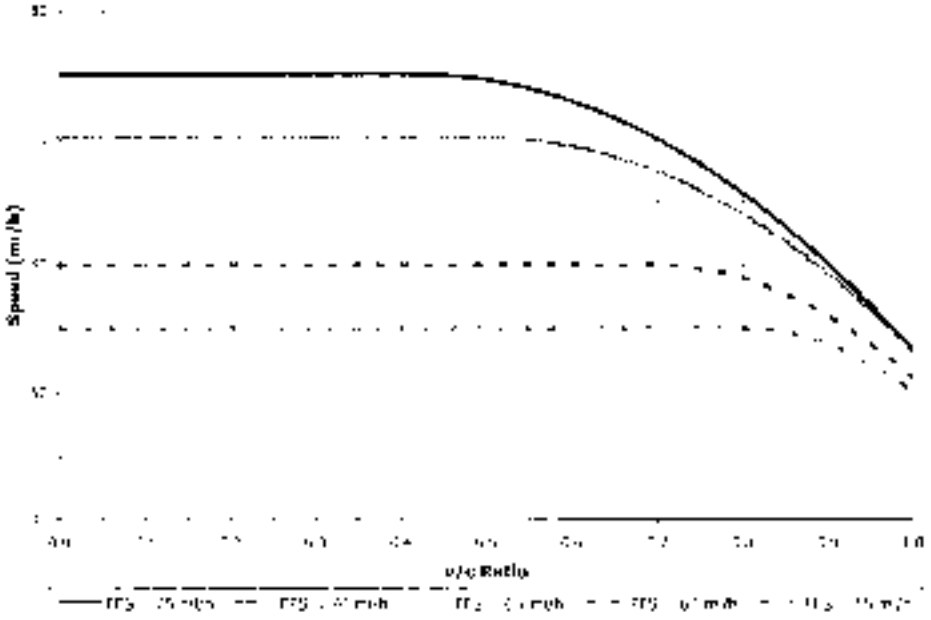
Each on- and off-ramp in the direction of travel is counted when total ramp density is determined.

Higher total ramp densities represent suburban and urban situations as well as the type of interchanges present. Most interchanges involve two to four ramps. A full cloverleaf, for example, has four ramps: two on-ramps and two off-ramps in each direction. A diamond interchange has two ramps in each direction, one on-ramp and one off-ramp. Thus, a freeway with two cloverleaf interchanges fully contained within 1 mi would have a total ramp density of 8 ramps/mi. A freeway with two diamond interchanges fully contained within 1 mi would have a total density of 4 ramps/mi. This finding suggests that in any given situation (with comparable demand flows), cloverleaf interchanges will have a greater negative impact on FFS than diamond interchanges.

Although Exhibit 11-14 is not a straight line, the slope is relatively constant. On average, an increase of 2 ramps/mi in total ramp density causes a drop in FFS of approximately 3 mi/h. A reduction in FFS, of course, implies reductions in capacity and service volumes.

Exhibit 11-15 shows the relationship between speed and v/c ratio. Not unexpectedly, the shapes of these curves are similar to the basic speed–flow curves of Exhibit 11-2. Speed does not begin to decline until a v/c ratio of 0.42 to 0.80 is reached, depending on the FFS.

Exhibit 11-15
Speed Versus v/c Ratio



AR0073526

3. APPLICATIONS

The methodology in the chapter is relatively straightforward, so it can be directly used in any one of four applications:

1. *Operational analysis.* All traffic and roadway conditions are specified for an existing facility or a future facility with forecast conditions. The existing or expected LOS is determined.
2. *Design analysis.* A forecast demand volume is used, and key design parameters are specified (e.g., lane width and lateral clearance). The number of lanes required to deliver a target LOS is determined.
3. *Planning and preliminary engineering.* The basic scenario is the same as that for design analysis, except that the analysis is conducted at a much earlier stage of the development process. Inputs include default values, and the demand volume is usually stated as an annual average daily traffic (AADT) value.
4. *Service flow rates and service volumes.* The service flow rate, service volume, or daily service volume, or all three, are estimated for each LOS for an existing or future facility. All traffic and roadway conditions must be specified for this type of analysis.

Because the methodology and its algorithms are simple and do not involve iterations, all of the types of analysis cited can be done without the trial-and-error approach required by many other *Highway Capacity Manual* (HCM) methodologies.

DEFAULT VALUES

In using this chapter's methodology, a range of input data is needed. Most of these data should be field-measured or estimated values for the specific segment under consideration. When some of the data are not available, default values may be used. However, the use of default values will affect the accuracy of the output. Exhibit 11-16 shows the data that are required to conduct an operational analysis and the recommended default values when site-specific data are unavailable (*1*).

Exhibit 11-16
Required Input Data and Default Values for Basic Freeway Segments

Required Data	Default Values
Geometric Data	
Number of lanes in one direction	No default; must have site-specific value
Lane width (ft)	12 ft
Right-side lateral clearance (ft)	10 ft
Ramp density (ramps/mi)	No default; must have site-specific value
Terrain or specific grade (%, length)	No default; must have site-specific value
FFS (mi/h)	Urban, 70 mi/h; rural, 75 mi/h
Demand Data	
Length of analysis period (min)	15 min
PHF	0.94
Proportion of heavy vehicles (%)	Urban, 5%; rural, 12%*
Driver population factor	1.00

* Alternative state-specific default values for percentage of heavy vehicles are given in Chapter 26.

AR0073527

The analyst may also replace the default values of Exhibit 11-16 with defaults that have been locally calibrated.

Research into the percentage of heavy vehicles on uninterrupted flow facilities (13) found a wide range of average values from state to state. Chapter 26 provides alternative default values for percentage of heavy vehicles by state and area population on the basis of data from the 2004 Highway Performance Monitoring System. Where states or local jurisdictions have developed their own values, these may be substituted. Analysts may also wish to develop their own default values based on more recent data.

ESTABLISH ANALYSIS BOUNDARIES

Determining capacity or LOS requires uniform traffic and roadway conditions on the analysis segment. Thus, any point where roadway or traffic conditions change must mark a boundary of the analysis segment.

Ramp junctions, grade changes of 2% or more, changes in the roadway geometric characteristics, and changes in speed limit are points where basic freeway segment boundaries should be established.

At every ramp–freeway junction, the demand volume changes (as some vehicles enter or leave the traffic stream). Thus, any ramp junction should mark a boundary between adjacent basic freeway segments.

In addition to ramp–freeway junctions, the following conditions generally dictate that a boundary should be established between basic freeway segments:

- Change in the number of lanes (cross section),
- Changes in lane width or lateral clearance,
- Grade change of 2% or more on a specific or composite grade,
- Change in terrain category (for general terrain segments), or
- Change in posted speed limit.

The last is not directly involved in the analysis of a basic freeway segment but would probably reflect changes in ramp density or other freeway features.

TYPES OF ANALYSIS

Operational Analysis

Operational analysis finds the expected LOS for specified roadway and traffic conditions.

The operational analysis application was fully specified in the Methodology section of this chapter. Operational analysis begins with all input parameters specified and is used to find the expected LOS that would result from the prevailing roadway and traffic conditions.

Design Analysis

Design analysis finds the number of lanes required for a target LOS, given a specified demand volume.

In design analysis, a known demand volume is used to determine the number of lanes needed to deliver a target LOS. Two modifications are required to the operational analysis methodology. First, since the number of lanes is to be determined, the demand volume is converted to a demand flow rate in passenger cars per hour, not per lane, using Equation 11-5 instead of Equation 11-2:

Equation 11-5

$$v_p = \frac{V}{PHF \times f_{HV} \times f_p}$$

AR0073528

where v is the demand flow rate in passenger cars per hour and all other variables are as previously defined.

Second, a maximum service flow rate for the target LOS is then selected from Exhibit 11-17. These values are selected from the base speed–flow curves of Exhibit 11-6 for each LOS.

Exhibit 11-17
Maximum Service Flow Rates in Passenger Cars per Hour per Lane for Basic Freeway Segments Under Base Conditions

FFS (mi/h)	Target Level of Service A	B	C	D	E
75	820	1,310	1,750	2,110	2,400
70	770	1,250	1,680	2,090	2,400
65	710	1,170	1,630	2,050	2,350
60	660	1,080	1,560	2,010	2,300
55	600	990	1,430	1,900	2,250

Note: All values rounded to the nearest 10 pc/h/ln.

Next, the number of lanes required to deliver the target LOS can be found from Equation 11-6:

$$N = \frac{v}{MSF_i} \quad \text{Equation 11-6}$$

where N is the number of lanes required and MSF_i is the maximum service flow rate for LOS i from Exhibit 11-17. Equation 11-5 and Equation 11-6 can be conveniently combined as Equation 11-7.

$$N = \frac{V}{MSF_i \times PHF \times f_{HV} \times f_p} \quad \text{Equation 11-7}$$

where all variables are as previously defined.

All fractional values of N must be rounded up.

The value of N resulting from Equation 11-6 or Equation 11-7 will most likely be fractional. Since only integer numbers of lanes can be constructed, the result is always rounded to the next-higher value. Thus, if the result is 3.2 lanes, 4 must be provided. The 3.2 lanes is, in effect, the minimum number of lanes required to provide the target LOS. If the result were rounded to 3, a poorer LOS than the target value would result.

Because only whole lanes can be built, it may not be possible to achieve the target LOS for a given demand volume.

This rounding-up process will occasionally produce an interesting result: it is possible that a target LOS (for example, LOS C) cannot be achieved for a given demand volume. If 2 lanes are required to produce LOS C, providing 2 lanes would drop the LOS, most likely to D. However, if three lanes are provided, the LOS might actually improve to B. Thus, some judgment may be required to interpret the results. In this case, two lanes might be provided even though they would result in a lower-than-LOS C. Economic considerations might lead a decision maker to accept a slightly lower operating condition than that originally targeted.

Planning and Preliminary Engineering

Planning and preliminary engineering applications use both the number of lanes required to deliver a target LOS and prepare more generalized input values to the methodology.

The objective of planning or preliminary engineering is to get a general idea of the number of lanes that will be required to deliver a target LOS. The primary differences are that many default values will be used and the demand volume will be usually expressed as an AADT. Thus, a planning and preliminary engineering analysis starts by converting the demand expressed as an AADT to

AR0073529

an estimate of the directional peak-hour demand volume (DDHV) with Equation 11-8:

Equation 11-8

$$V_{DDHV} = AADT \times K \times D$$

where K is the proportion of AADT occurring during the peak hour and D is the proportion of peak hour volume traveling in the peak direction; all other variables are as previously defined.

Chapter 3 provides additional guidance on K- and D-factors.

On urban freeways, the typical range of K-factors is from 0.08 to 0.10. On rural freeways, values typically range between 0.09 and 0.12. Directional distributions also vary, as was illustrated in Chapter 3, Modal Characteristics, but a typical value for both urban and rural freeways is 0.55. As with all default values, locally or regionally calibrated values are preferred and yield more accurate results. Both the K-factor and the D-factor have a significant impact on the estimated hourly demand volume.

Once the hourly demand volume is estimated, the methodology follows the same path as that for design analysis.

Service Flow Rates, Service Volumes, and Daily Service Volumes

This chapter's methodology can be easily manipulated to produce service flow rates, service volumes, and daily service volumes for a basic freeway segment.

Exhibit 11-17 gives values of the maximum service flow rates, MSF_i, for each LOS for freeways of various FFSs. These values are given in terms of passenger cars per hour per lane under equivalent base conditions. A service flow rate, SF_i, is the maximum rate of flow that can exist while LOS *i* is maintained during the 15-min analysis period under prevailing conditions. It can be computed from the maximum service flow rate by using Equation 11-9:

Equation 11-9

$$SF_i = MSF_i \times N \times f_{HV} \times f_p$$

where all variables are as previously defined.

A service flow rate can be converted to a service volume, SV_i, by applying a PHF as shown in Equation 11-10. A service volume is the maximum hourly volume that can exist while LOS *i* is maintained during the worst 15-min period of the analysis hour.

Equation 11-10

$$SV_i = SF_i \times PHF$$

where all variables are as previously defined.

A daily service volume, DSV_i, is the maximum AADT that can be accommodated by the facility under prevailing conditions while LOS *i* is maintained during the worst 15-min period of the analysis day. It is estimated from Equation 11-11:

Equation 11-11

$$DSV_i = \frac{SV_i}{K \times D}$$

where all variables are as previously defined.

AR0073530

Service flow rates SF and service volumes SV are stated for a single direction of the freeway. Daily service volumes DSV are stated as total volumes in both directions of the freeway.

USE OF ALTERNATIVE TOOLS

General guidance for the use of alternative traffic analysis tools for capacity and LOS analysis is provided in Chapter 6, HCM and Alternative Analysis Tools. This section contains specific guidance for the application of alternative tools to the analysis of basic freeway segments. Additional information on this topic may be found in Chapter 26, Basic Freeway Segments: Supplemental.

Strengths of HCM Procedure

The HCM methodology provides FFS as an output. Simulators generate characteristics, calculate model capacity estimates, and produce a single deterministic estimate of traffic density.

This chapter's procedures were developed on the basis of extensive research supported by a significant quantity of field data. They have evolved over a number of years and represent a body of expert consensus.

Specific strengths of the HCM basic freeway segment methodology include the following:

- It provides a detailed methodology for obtaining FFS. This methodology is based on various geometric characteristics. In simulation packages, FFS (or an equivalent, such as desired speed) is an input.
- It accounts for geometric characteristics (such as lane width), which are rarely, if ever, incorporated into simulation algorithms.
- It provides explicit capacity estimates. Simulation packages do not provide capacity estimates directly. Capacity estimates can only be obtained from simulations through multiple runs with oversaturated conditions. The user can modify simulated capacities by supplying specific input values such as the minimum acceptable headway.
- It produces a single deterministic estimate of traffic density, which is important for some purposes such as development impact review.

Limitations of HCM Procedures That Might Be Addressed by Alternative Tools

Deterministic models yield the same results for the same inputs each time they are implemented; stochastic models incorporate statistical variability. For such inputs, different results in each run. For such models, an average result of X cycles is considered as output.

Basic freeway segments can be analyzed by using a variety of stochastic and deterministic simulation packages that include freeways. These packages can be very useful in analyzing the extent of congestion when there are features within the simulated facility range and when interaction with other freeway segments and other facilities is present.

Exhibit 11-18 tabulates the HCM limitations for basic freeway segments along with the potential for improved treatment by alternative tools.

Additional Features and Performance Measures Available from Alternative Tools

This chapter provides a methodology for estimating the capacity, speed, and density of a basic freeway segment, given the segment's traffic demand and characteristics. Alternative tools offer additional performance measures,

AR0073531

including delay, stops, queue lengths, fuel consumption, pollution, and operating costs.

Exhibit 11-18
Limitations of HCM Basic Freeway Segments Procedure

Limitation	Potential for Improved Treatment by Alternative Tools
Special lanes reserved for a single vehicle type, such as HOV, truck, and climbing lanes	Modeled explicitly by simulation
Extended bridge and tunnel segments	Can be approximated by using assumptions related to desired speed and number of lanes along each segment
Segments near a toll plaza	Can be approximated by using assumptions related to discharge at toll plaza
Facilities with FFS less than 55 mi/h or more than 75 mi/h	Modeled explicitly by simulation
Oversaturated conditions (refer to Chapters 10 and 26 for further discussion)	Modeled explicitly by simulation
Influence of downstream blockages or queuing on a segment	Modeled explicitly by simulation
Posted speed limit and extent of police enforcement	Can be approximated by using assumptions related to desired speed along a given segment
Presence of ITS features related to vehicle or driver guidance	Several features modeled explicitly by simulation, others may be approximated by using assumptions (for example, by modifying origin–destination demands by time interval)

As with most other procedural chapters in the HCM, simulation outputs, especially graphics-based presentations, can provide details on point problems that might otherwise go unnoticed with a macroscopic analysis that yields only segment level measures. The effect of downstream conditions on lane utilization and backup beyond the segment boundary is a good example of a situation that can benefit from the increased insight offered by a microscopic model.

Development of HCM-Compatible Performance Measures Using Alternative Tools

The LOS for basic freeway segments is based on traffic density expressed in passenger cars per mile per lane. The HCM methodology estimates density by dividing the flow rate by the average passenger-car speed. Simulation models typically estimate density by dividing the average number of vehicles in the segment by the area of the segment (in lane miles). The result is vehicles per lane mile. This measurement corresponds to density based on space mean speed. The HCM-reported density is also based on space mean speed, but because there is no variability in the speeds, the space mean speed is equal to the time mean speed. Generally, increased speed variability in driver behavior (which simulators usually include) results in lower average space mean speed and higher density.

In obtaining density from alternative models, it is important to take into account the following:

- The vehicles included in the density estimation (for example, was that only the vehicles that have exited the link are considered);
- The manner in which auxiliary lanes are considered;

AR0073532

- The units used for density, since a simulation package would typically provide density in units of vehicles rather than passenger cars; converting the simulation outputs to passenger cars with the HCM PCE values is typically not appropriate, given that the simulation should already account for the effects of heavy vehicles on a microscopic basis—with heavy vehicles operating at lower speeds and at longer headways—thus making any additional adjustments duplicative;
- The units used in the reporting of density (e.g., whether it is reported per lane only);
- The homogeneity of the analysis segment, since the HCM does not use the segment length as an input (unless it is a specific upgrade or downgrade segment, where the length is used to estimate the PCE values), and conditions are assumed to be homogeneous for the entire segment; and
- The driver variability assumed in the simulation package, since increased driver variability will generally increase the average density.

Regarding capacity, the HCM provides capacity estimates in passenger cars per hour per lane as a function of FFS. To compare the HCM's estimates with capacity estimates from a simulation package, the following should be considered:

- The manner in which a simulation package provides the number of vehicles exiting a segment; in some cases it may be necessary to provide virtual detectors at a specific point on the simulated segment so that the maximum throughput can be obtained;
- The units used to specify maximum throughput, since a simulation package would do this in units of vehicles rather than passenger cars, converting these to passenger cars by using the HCM PCE values is typically not appropriate, since differences between automobile and heavy-vehicle performance should already be accounted for microscopically within a simulation; and
- The incorporation of other simulation inputs, such as the "minimum separation of vehicles," that affect the capacity result.

Conceptual Differences Between HCM and Simulation Modeling That Preclude Direct Comparison of Results

The HCM's methodology is based on the relationship between speed and flow for various values of FFS. One fundamental potential difference between the HCM and other models is this relationship. For example, the HCM assumes a constant speed for a broad range of flows. However, this is not necessarily the case for any given simulation package, some of which assume a continuously decreasing speed with increasing flow. Furthermore, in some simulation packages, that relationship changes when certain parameters are modified. Therefore, if performance measures are compared between the HCM and an alternative model for a given set of flows, this will not necessarily be the case for all other sets of flows.

AR0073533

Adjustment of Simulation Parameters to HCM Results

The most important elements to be adjusted when a basic freeway segment is analyzed are the speed–flow relationship or the capacity, or both. The speed–flow relationship should be examined as a function of the given FFS. That FFS should match the field- or HCM-estimated value. Some tools only accept integer values of FFS, whereas the HCM may provide a fractional value as an intermediate calculation result.

Step-by-Step Recommendations for Applying Alternative Tools

This section provides recommendations specifically for freeway segments (general guidance on selecting and applying simulation packages is provided in Chapter 6, HCM and Alternative Analysis Tools). To apply an alternative tool to the analysis of basic freeway segments, the following steps should be taken:

1. Determine whether the chosen tool can provide density and capacity for a basic freeway segment and the approach used to obtain those values. Once the analyst is satisfied that density and capacity can be obtained and that values compatible with those of the HCM can also be obtained, proceed with the analysis.
2. Determine the FFS of the study site either from field data or by estimating it according to this chapter's methodology.
3. Enter all available geometric and traffic characteristics into the simulator package and install virtual detectors along the study segment, if necessary, to obtain speeds and flows.
4. By loading the study network over capacity, obtain the maximum throughput and compare it with the HCM estimate. Calibrate the simulation package by modifying parameters related to the maximum flow headway, so that the capacity obtained by the simulator closely matches the HCM estimate. Estimate the required number of runs to be conducted so that the comparison is statistically valid.
5. If the analysis requires evaluating various different demand conditions for the segment, plot the simulator's speed–flow curve and compare it with the HCM relationship. Attempt to calibrate the simulation package by modifying parameters related to driver behavior, such as the distribution of driver types. It is possible that the simulator cannot be calibrated to match the HCM speed–flow relationship. In that case, the results should be viewed with caution in terms of their compatibility with the HCM methods.

Sample Calculations Illustrating Alternative Tool Applications

Chapter 26, in Volume 4 of the HCM, provides two supplemental problems that examine situations beyond the scope of this chapter's methodology by using a typical microsimulation-based tool. Both problems are based on Example Problem 3 (found in the next section of this chapter), which analyzes a six-lane freeway segment in a growing urban area. The first supplemental problem evaluates the facility when an HOV lane is added, and the second problem analyzes operations with an incident within the segment.

AR0073534

4. EXAMPLE PROBLEMS

Exhibit 11-19
List of Example Problems

Example Problem	Description	Application
1	Four-lane freeway LOS	Operational analysis
2	Number of lanes required for target LOS	Design analysis
3	Six-lane freeway LOS and capacity	Operational and planning analysis
4	LOS on upgrades and downgrades	Operational analysis
5	Design hour volume and number of lanes	Planning analysis
6	Service flow rates and service volumes	Planning analysis

EXAMPLE PROBLEM 1: FOUR-LANE FREEWAY LOS

The Facts

- Four-lane freeway (two lanes in each direction);
- Lane width = 11 ft;
- Right-side lateral clearance = 2 ft;
- Commuter traffic (regular users);
- Peak hour, peak-direction demand volume = 2,000 veh/h;
- Traffic composition: 5% trucks, 0% RVs;
- PHF = 0.92;
- One cloverleaf interchange per mile; and
- Rolling terrain.

Comments

The task is to find the expected LOS for this freeway during the worst 15 min of the peak hour. With one cloverleaf interchange per mile, the total ramp density will be 4 ramps/mi.

Step 1: Input Data

All input data are specified above.

Step 2: Compute FFS

The FFS of the freeway is estimated as follows:

$$FFS = 75.4 - f_{LW} - f_{LC} - 3.22\,TRD^{0.84}$$

The adjustment for lane width is selected from Exhibit 11-8 for 11-ft lanes (1.9 mi/h). The adjustment for right-side lateral clearance is selected from Exhibit 11-9 for a 2-ft clearance on a freeway with two lanes in one direction (2.4 mi/h). The total ramp density is 4 ramps/mi. Then

$$FFS = 75.4 - 1.9 - 2.4 - 3.22\left(4^{0.84}\right) = 60.8 \text{ mi/h}$$

Step 3: Select FFS Curve

As the FFS calculated in Step 2 is greater than or equal to 57.5 and less than 62.5 mi/h, the 60-mi/h speed–flow curve will be used for this analysis.

AR0073535

Step 4: Adjust Demand Volume

The demand volume must be adjusted to a flow rate that reflects passenger cars per hour per lane under equivalent base conditions by using Equation 11-7:

$$v_p = \frac{V}{PHF \times N \times f_{HV} \times f_p}$$

The demand volume is given as 2,000 veh/h. The PHF is specified to be 0.92, and there are two lanes in each direction. The driver population factor is 1.00, since regular users (commuters) are also specified. Trucks make up 5% of the traffic stream, so a heavy-vehicle adjustment factor must be determined.

From Exhibit 11-10, the PCE for trucks is 2.5 for rolling terrain. The heavy-vehicle adjustment factor is then computed by using Equation 11-9:

$$f_{HV} = \frac{1}{1 + P_T (E_T - 1) + P_R (E_R - 1)}$$

$$f_{HV} = \frac{1}{1 + 0.05(2.5 - 1) + 0} = 0.930$$

Then,

$$v_p = \frac{2{,}000}{0.92 \times 2 \times 0.93 \times 1.00} = 1{,}169 \text{ pc/h/ln}$$

Since this value is less than the base capacity of 2,300 pc/h/ln for a freeway with FFS = 60 mi/h, LOS F does not exist, and the analysis continues to Step 5.

Step 5: Estimate Speed and Density

The FFS of the basic freeway segment is now estimated along with the demand flow rate in passenger cars per hour per lane under equivalent base conditions. From Exhibit 11-3, the equation for estimating the speed of the traffic stream is selected for a 60-mi/h FFS, with a flow rate less than 1,600 pc/h/ln. This is the constant-speed portion of the curve, or $S = 60$ mi/h. The density of the traffic stream may now be computed as:

$$D = \frac{v_p}{S} = \frac{1{,}169}{60} = 19.5 \text{ pc/mi/ln}$$

Step 6: Determine LOS

From Exhibit 11-5, a density of 19.5 pc/mi/ln corresponds to LOS C but is close to the boundary for LOS B, which is a maximum of 18 pc/mi/ln. This solution could also be calculated graphically by using Exhibit 11-6 as a base (Exhibit 11-20).

AR0073536

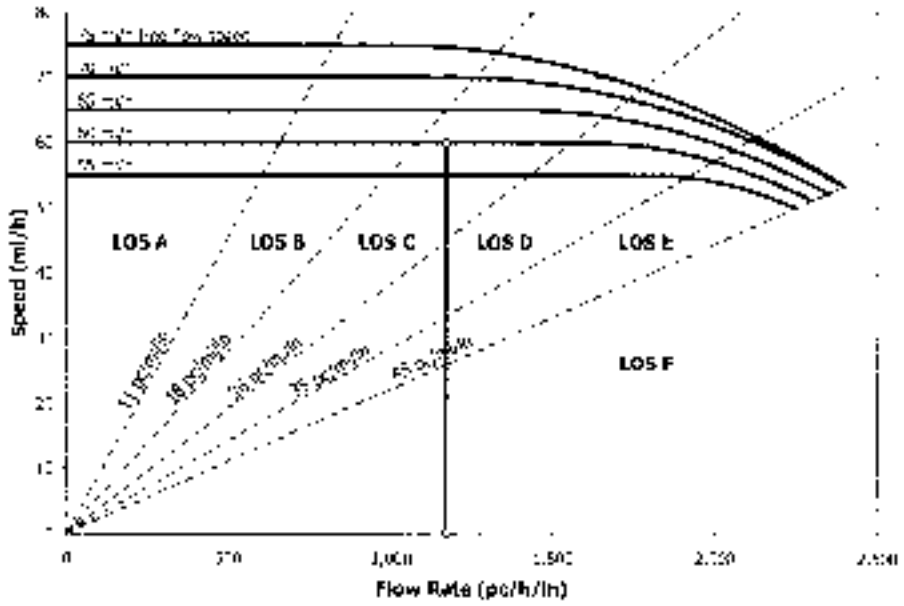


Exhibit 11-20
Graphical Solution for Example Problem 2

Discussion

The base freeway segment of a four-lane freeway is expected to operate at LOS C during the worst 15 min of the peak hour. It is important to note that the operation, although at LOS C, is close to the LOS B boundary. In most jurisdictions, this operation would be considered to be quite acceptable; therefore, no remediation would normally be required.

EXAMPLE PROBLEM 2: NUMBER OF LANES REQUIRED FOR TARGET LOS

The Facts

- Demand volume = 4,000 veh/h (one direction),
- Level terrain,
- Traffic composition: 15% trucks, 3% RVs,
- Provision of 12-ft lanes,
- Provision of 6-ft right-side lateral clearance,
- Commuter traffic (regular users),
- PHF = 0.85,
- Ramp density = 3 ramps/mi, and
- Target LOS = D.

Comments

This is a classic design application of the methodology. The number of lanes needed to provide LOS D during the worst 15 min of the peak hour is to be determined.

Step 1: Input Data

All input data were specified previously.

AR0073537

Step 2: Compute FFS

The FFS is estimated by using Equation 11-1. Because the lane width and lateral clearance to be provided on the new freeway will be 12 ft and 6 ft, respectively, there are no adjustments for these features. The total ramp density is given as 3 ramps/mi. Then

$$FFS = 75.4 - f_{LW} - f_{LC} - 3.22TRD^{0.84}$$

$$FFS = 75.4 - 0.0 - 0.0 - 3.22(3^{0.84}) = 67.3 \text{ mi/h}$$

Step 3: Select FFS Curve

Since the FFS calculated in Step 2 is greater than or equal to 62.5 and less than 67.5 mi/h, the 65-mi/h speed–flow curve will be used for this analysis.

Step 4: Estimate Number of Lanes Needed

Because this is a design analysis, Step 4 of the operational analysis methodology is modified. Equation 11-7 may be used directly to determine the number of lanes needed to provide no at least LOS D.

$$N = \frac{V}{MSF_i \times PHF \times f_{HV} \times f_p}$$

A value of the maximum service flow rate must be selected from Table 11-17 for a FFS of 65 mi/h and LOS D. This value is 2,030 pc/h/ln. The PHF is given as 0.85. The driver population factor is 1.00, since commuters are involved. A heavy-vehicle factor for 15% trucks and 3% RVs must be determined by using Exhibit 11-10 for level terrain. The PCEs of trucks and RVs in level terrain are 1.5 and 1.2, respectively. Then

$$f_{HV} = \frac{1}{1 + P_T(E_T - 1) + P_R(E_R - 1)}$$

$$f_{HV} = \frac{1}{1 + 0.15(1.5 - 1) + 0.03(1.2 - 1)} = 0.925$$

and

$$N = \frac{4{,}000}{2030 \times 0.85 \times 0.925 \times 1.00} = 2.51 \text{ lanes}$$

It is not possible to build 2.51 lanes. To provide a minimum of LOS D, it will be necessary to provide three lanes in each direction, or a six-lane freeway.

At this point, the design application ends. It is possible, however, to consider what speed, density, and LOS will prevail when three lanes are actually provided. Therefore, the example problem continues with Steps 5 and 6.

Step 5: Estimate Speed and Density

In pursuing additional information, the problem now reverts to an operational analysis of a three-lane basic freeway segment with a demand volume of 4,000 pc/h.

AR0073538

Equation 12-2 is used to compute the actual demand flow rate per lane under equivalent base conditions:

$$v_p = \frac{V}{PHF \times N \times f_{HV} \times f_p}$$

$$v_p = \frac{4,000}{0.85 \times 3 \times 0.925 \times 1.00} = 1,696 \text{ pc/h/ln}$$

The expected speed of the traffic stream may be estimated either by using Exhibit 11-6 (for a graphical solution) or by selecting the appropriate equation from Exhibit 11-3—in this case, using FFS = 65 mi/h and a demand flow rate over 1,400 pc/h/ln. With the latter approach,

$$S = 65 - 0.0000147(v_p - 1,400)^2$$

$$S = 65 - 0.0000147(1,696 - 1,400)^2 = 63.8 \text{ mi/h}$$

The density may now be computed:

$$D = \frac{v_p}{S} = \frac{1,696}{63.8} = 26.6 \text{ pc/mi/ln}$$

Step 6: Determine LOS

Entering Exhibit 11-5 with a density of 26.6 pc/mi/ln, the LOS is D but is very close to the boundary of LOS C, which is 26 pc/mi/ln.

Discussion

The resulting LOS is D, which was the target for the design. Although the minimum number of lanes needed was 2.51, which would have provided for a minimal 2.0 LOS, providing three lanes yields a density that is close to the LOS C boundary. In any event, the target LOS of the design will be met by providing a six-lane basic freeway segment.

EXAMPLE PROBLEM 3: SIX-LANE FREEWAY LOS AND CAPACITY

The Facts

- Volume of 5,000 veh/h (one direction, existing);
- Volume of 5,600 veh/h (one direction, in 3 years);
- Traffic composition: 10% trucks, no RVs;
- Level terrain;
- Three lanes in each direction;
- FFS = 70 mi/h (measured);
- PHF = 0.95;
- Commuter traffic (regular users); and
- Traffic growth after 3 years = 4% per year.

AR0073539

Comments

This example consists of two operational analyses, one for the present demand volume of 5,030 pc/h and one for the demand volume of 5,600 pc/h expected in 3 years. In addition, a planning element is introduced. Assuming that traffic grows as expected, when will the capacity of the roadway be exceeded? This analysis requires that capacity be determined in addition to the normal output of operational analyses.

Step 1: Input Data

All input data were given previously.

Step 2: Compute FFS

Step 2 is not needed since a measured FFS is given (70 mi/h).

Step 3: Select FFS Curve

Step 3 is not needed. The FFS curve for 70 mi/h will be used, based on the measured value.

Step 4: Adjust Demand Volume

In this case, two demand volumes will be adjusted by using Equation 11-2:

$$v_p = \frac{V}{PHF \times N \times f_{HV} \times f_p}$$

The PHF is given as 0.95, and there are three lanes in each direction. The driver population adjustment factor will be 1.00 for regular users. The heavy vehicle factor must reflect 10% trucks in level terrain. From exhibit 11-10, the PCE for trucks in level terrain is 1.5. Equation 11-3 then gives the following:

$$f_{HV} = \frac{1}{1 + P_T (E_T - 1) + P_R (E_R - 1)}$$

$$f_{HV} = \frac{1}{1 + 0.10(1.5 - 1) - 0} = 0.952$$

Two values of v_p will be computed, one for present conditions and one for conditions in 5 years:

$$v_p \text{ (present)} = \frac{5,030}{0.95 \times 3 \times 0.952 \times 1.00} = 1,843 \text{ pc/h}$$

$$v_p \text{ (future)} = \frac{5,600}{0.95 \times 3 \times 0.952 \times 1.00} = 2,064 \text{ pc/h}$$

AR0073540

Step 5: Estimate Speed and Density

Two values of speed and density will be estimated, one each for the present and future conditions stated. The equations of Exhibit 11-3 will be used to estimate speeds. One equation applies to both cases, a 70-mi/h FFS with a flow rate of or 1,200 pc/h/ln:

$$S(\text{present}) = 70 - 0.00780(v_p - 1{,}200)^2$$

$$S(\text{present}) = 70 - 0.00780(1{,}843 - 1{,}200)^2 = 65.2 \text{ mi/h}$$

$$S(\text{future}) = 70 - 0.00780(v_p - 1{,}200)^2$$

$$S(\text{future}) = 70 - 0.00780(2{,}064 - 1{,}200)^2 = 61.3 \text{ mi/h}$$

The corresponding densities may now be estimated as follows:

$$D = \frac{v_p}{S}$$

$$D(\text{present}) = \frac{1{,}843}{65.2} = 28.3 \text{ pc/mi/ln}$$

$$D(\text{future}) = \frac{2{,}064}{61.3} = 33.7 \text{ pc/mi/ln}$$

Step 6: Determine LOS

From Exhibit 11-5, the LOS for the present situation is D, and the LOS for the future situation (in 5 years) is also D, despite the increase in density.

Step 7: When Will Capacity Be Reached?

Step 7 is an additional step for this problem. To answer the question, the capacity of the basic freeway segment must be estimated. From Exhibit 11-17, the maximum service flow rate for LOS E on a basic freeway segment with a 70 mi/h FFS is 2,400 pc/h/ln. This flow rate is synonymous with capacity.

The analyst must be sure that the capacity and demand flow rates compared in Step 7 are on the same basis. The 2,400 pc/h/ln is a flow rate under equivalent base conditions. The demand flow rate in 5 years was estimated to be 2,064 pc/h/ln on this basis. These two values, therefore, may be compared. As an alternative, the capacity could be computed for prevailing conditions:

$$SF_i = MSF_i \times N \times f_{HV} \times f_p$$

$$SF_i = 2{,}400 \times 3 \times 0.952 \times 1.00 = 6{,}854 \text{ veh/h}$$

This capacity, however, is stated as a *flow rate*. The demand volume is stated as an hourly volume. Thus, a service volume for LOS E is needed:

$$SV_i = SF_i \times PHF = 6{,}854 \times 0.95 = 6{,}511 \text{ veh/h}$$

The problem may be solved either by comparing the demand volume of 5,000 veh/h (in 5 years) with the hourly capacity of 6,511 veh/h or by comparing the demand flow rate under equivalent base conditions of 2,064 pc/h/ln with the

AR0073541

base capacity of 2,400 pc/h/ln. With the hourly demand volume and hourly capacity,

$$6{,}511 = 5{,}600(1.04)^n$$

$$n = 3.85 \text{ years}$$

On the basis of the forecasts of traffic growth, the basic freeway segment described will reach capacity within 4 years (the demand of 5,600 veh/h occurs 3 years from the present).

Discussion

The LOS on this segment will remain D within 3 years despite the increase in density. The demand is expected to exceed capacity within 4 years. Given the normal lead times for planning, design, and approvals before the start of construction, it is probable that planning and preliminary design for an improvement should be started immediately.

EXAMPLE PROBLEM 4: LOS ON UPGRADES AND DOWNGRADES

The Facts

- Demand volume = 2,300 veh/h (one direction);
- Traffic composition: 15% trucks, no RVs;
- PHF = 0.90;
- FFS = 70 mi/h upgrade, 75 mi/h downgrade (measured);
- Unfamiliar drivers (f_p = 0.95); and
- Composite grade: 3,700 ft at 3%, followed by 2,600 ft at 5%.

Comments

This is a typical operational analysis. The expected outcome is an assessment of the LOS on both the upgrade and the downgrade. However, the problem deals with a specific grade and a composite grade. Because there is a segment of the grade that is greater than 4% and the total length of the composite grade exceeds 4,000 ft, the special procedure in Appendix A must be applied. That procedure will yield an equivalent constant percent grade of $(3{,}700 + 2{,}600 - 5{,}000)$ ft (1.08 mi), which has the same impact on heavy vehicles as the composite grade described.

Composite Grade

Exhibit 11-21 shows the conversion of the composite grade to a grade of constant percent 5,600 ft long. At the end of such a grade, the final speed of heavy vehicles is approximately the same as that on the composite grade.

A vertical line enters the truck performance curves at 3,000 ft corresponding to the 3% grade curve, indicating that the speed of trucks after 3,000 ft of 4.8% grade is approximately 42 mi/h. This is also the speed at which the truck enters the 5% grade; it corresponds to the same speed as that of a truck on a 4.8% grade after 1,300 ft. The truck travels another 2,600 ft (to 5,900 ft) on the 5% curve.

AR0073542

where a final speed of 27 mi/h is reached. The intersection of a horizontal drawn at 27 mi/h and a vertical drawn at a total length of grade of 5,600 ft yields the equivalent of +5%. In effect, because trucks on this grade are at crawl speed, it does not matter how long the grade is; 27 mi/h can be maintained indefinitely.

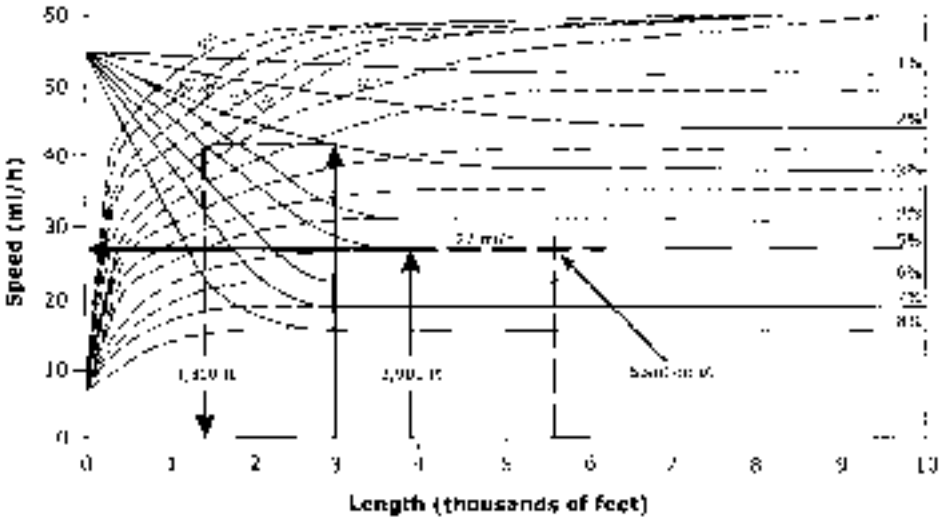

Exhibit 11-21
Determination of Composite Grade Equivalents for Example Problem 4

The equivalent grade is +5%, 5,600 ft. This equivalent should be applied to *both the upgrade and the downgrade*, even though it was developed specifically for the upgrade.

Although the truck acceleration curves of Appendix A could be used to develop a separate downgrade composite equivalent, it would be very misleading. The truck performance curves assume a maximum speed of 60 mi/h. On a long, steep downgrade, trucks will achieve much higher speeds.

It is highly likely that trucks will be forced to use a low gear to apply engine braking on the grade described. Thus, PCEs for the downgrade will be selected from Exhibit 11-18.

Step 1: Input Data

All input data were specified previously.

Step 2: Compute FFS

FFSs were measured in the field. The upgrade FFS is 70 mi/h; the downgrade FFS is 75 mi/h.

Step 3: Select FFS Curve

The 70-mi/h curve will be used for the upgrade; the 75-mi/h curve will be used for the downgrade.

Step 4: Adjust Demand Volume

The demand flow rates in passenger cars per hour per lane for the upgrade and downgrade are estimated by using Equation 11-2:

AR0073543

$$v_p = \frac{V}{PHF \times N \times f_{HV} \times f_p}$$

The PHF is 0.90, there are two lanes on the upgrade and two lanes on the downgrade, and f_p is specified as 0.95. Heavy-vehicle adjustment factors, however, must be determined separately for the upgrade and the downgrade.

The PCE for trucks (E_T) on the upgrade is selected from Exhibit 11-11 for a grade of 5%, >1.00 mi long, with 17% trucks: 3.0. The PCE for the trucks on the downgrade is selected from Exhibit 11-15 for a grade of 4% to 5%, ≤4 mi long: 1.5.

The heavy-vehicle adjustment factors, f_{HV} are computed by using Equation 11-8:

$$f_{HV} = \frac{1}{1 + P_T(E_T - 1) + P_R(E_R - 1)}$$

$$f_{HV}\text{ (upgrade)} = \frac{1}{1 + 0.15(3 - 1) + 0} = 0.769$$

$$f_{HV}\text{ (downgrade)} = \frac{1}{1 + 0.15(1.5 - 1) + 0} = 0.930$$

Then

$$v_p\text{ (upgrade)} = \frac{2{,}300}{0.90 \times 2 \times 0.769 \times 0.95} = 1{,}749\text{ pc/h/ln}$$

$$v_p\text{ (downgrade)} = \frac{2{,}300}{0.90 \times 2 \times 0.930 \times 0.95} = 1{,}446\text{ pc/h/ln}$$

Since neither of these values exceeds the base capacity of a freeway with FFS = 75 mi/h (downgrade) or FFS = 70 mi/h (upgrade), LOS F does not exist, and the analysis continues to Step 5.

Step 5: Estimate Speed and Density

With the FFS and the demand flow rates determined for both the upgrade and the downgrade, the expected speed and density on each may now be estimated. Speed is estimated by using the equations of Exhibit 11-3.

For the upgrade, the FFS is 70 mi/h, and the demand flow rate is greater than 1,200 pc/h/ln. Then

$$S = 70 - 0.00001160(v_p - 1{,}200)^2$$

$$S = 70 - 0.00001160(1{,}749 - 1{,}200)^2 = 66.5\text{ mi/h}$$

For the downgrade, the FFS is 75 mi/h, and the demand flow rate is greater than 1,000 pc/h/ln. Then

$$S = 75 - 0.00001107(v_p - 1{,}000)^2$$

$$S = 75 - 0.00001107(1{,}446 - 1{,}000)^2 = 72.8\text{ mi/h}$$

AR0073544

Densities may now be estimated from the demand flow rates and estimated speeds:

$$D = \frac{v_p}{S}$$

$$D(\text{upgrade}) = \frac{1,749}{66.5} = 26.3 \text{ pc/mi/ln}$$

$$D(\text{downgrade}) = \frac{1,446}{72.8} = 19.9 \text{ pc/mi/ln}$$

Step 6: Determine LOS

As shown in Exhibit 11-5, the upgrade LOS is D; the downgrade LOS is C. Both levels, however, are close to the boundaries for better operations. The upgrade is close to the boundary for LOS C ($D = 26$ pc/mi/ln) and the downgrade is close to the boundary for LOS B ($D = 18$ pc/mi/ln).

Discussion

Both the upgrade and the downgrade are operating at what would generally be called acceptable levels. If traffic grows over time, the addition of a truck climbing lane on the upgrade might be considered.

EXAMPLE PROBLEM 5: DESIGN-HOUR VOLUME AND NUMBER OF LANES

The Facts

- Demand volume = 75,000 veh/day,
- Proportion of AADT in the peak hour: 0.09,
- Directional distribution: 56/44,
- Rolling terrain, and
- Target LOS = D.

Comments

In this planning and preliminary engineering application, several input variables are not specified, so default values will have to be used. With knowledge of local conditions and freeway design standards, the following default values will be used in the solution: PHF = 0.95; truck = 6% mid; 5% trucks, no RVs; FHV = 0.95; and $f_p = 1.00$.

Determining Opening-Day Directional Design-Hour Volume

Because the demand volume is given as an AADT, it must be converted to a directional design-hour volume (DDHV) by using Equation 11-8:

$$v = DDHV = AADT \times K \times D$$

$$v = DDHV = 75,000 \times 0.09 \times 0.55 = 3,713 \text{ veh/h}$$

Step 1: Input Data

All input data were specified.

AR0073545

Step 2: Compute FFS

A default value of 65 mi/h will be used in this problem.

Step 3: Select FFS Curve

The 65-mi/h speed–flow curve will be used in this problem.

Step 4: Determine Number of Lanes Required

After estimating the demand volume on an hourly basis, the remainder of the solution follows the design application. The number of lanes needed is estimated by using Equation 11-7:

$$N = \frac{V}{MSF_i \times PHF \times f_{HV} \times f_p}$$

The maximum service flow rate is selected from Exhibit 11-17 for LOS D on a 65 mi/h basic freeway segment: 2,030 pc/h/ln. The PHF is a default value: 0.95. The driver population factor is also a default value: 1.00. The freeway is in rolling terrain and is expected to have 5% trucks (another default value). From Equation 11-10, for rolling terrain, $E_T = 2.5$. Then

$$f_{HV} = \frac{1}{1 + 0.05(2.5 - 1) + 0} = 0.930$$

$$N = \frac{3{,}713}{2{,}030 \times 0.95 \times 0.93 \times 1.00} = 2.07 \text{ lanes}$$

Because fractional lanes cannot be built, three lanes will have to be provided in each direction to ensure that LOS D is provided during the worst 15 min of the peak hour. Therefore, the resulting LOS may be better than the design target.

Step 5: Estimate Speed and Density

In order to determine the likely LOS resulting from a six-lane freeway, the speed and density should be estimated. Equation 11-2 is used to determine the actual demand flow rate for three lanes:

$$v_p = \frac{V}{PHF \times N \times f_{HV} \times f_p}$$

$$v_p = \frac{3{,}713}{0.95 \times 3 \times 0.93 \times 1.00} = 1{,}401 \text{ pc/h/ln}$$

From Exhibit 11-3, for a 65-mi/h basic freeway segment with more than 1,400 pc/h/ln, the expected speed is

$$S = 65 - 0.0000141838(v_p - 1{,}400)^2$$

$$S = 65 - 0.0000141838(1{,}401 - 1{,}400)^2 = 65.0 \text{ mi/h}$$

AR0073546

and the density is

$$D = \frac{v_p}{S} = \frac{1{,}401}{65.0} = 21.6 \text{ pc/mi/ln}$$

Step 6: Determine LOS

As shown in Exhibit 11-5, the expected LOS is C.

Discussion

This problem illustrates an interesting point: given the parameters of this example problem, the target LOS of D cannot be achieved on opening day. If a four-lane freeway (two lanes in each direction) is built, LOS E will result. If a six-lane freeway (three lanes in each direction) is built, LOS C will result.

EXAMPLE PROBLEM 6: SERVICE FLOW RATES AND SERVICE VOLUMES

The Facts

- Eight-lane freeway;
- FFS = 70 mi/h (measured);
- Traffic composition: 8% trucks, 1% RVs;
- Rolling terrain;
- PHF = 0.87;
- Driver population factor f_p = 1.00;
- Proportion of AADT in peak hour (*K*-factor): 10%; and
- Directional distribution (*D*-factor): 50/50.

Comments

In this problem, the service flow rate, service volume, and daily service volume for each LOS will be computed. These values could then be compared with any existing or forecast demand volumes to determine the LOS.

Step 1: Input Data

All input data were specified.

Step 2: Compute FFS

The FFS has been field-measured as 70 mi/h.

Step 3: Select FFS Curve

The curve for FFS = 70 mi/h will be used.

Step 4: Compute Service Flow Rates, *SF*

For a 70-mi/h basic freeway segment, maximum service flow rates, *MSF*, can be selected from Exhibit 11-17. These are the maximum service flow rates that can be maintained while a given LOS is maintained. They are stated as flow rates in passenger cars per hour per lane for equivalent base conditions. The values are

AR0073547

- MSF_1 = 770 pc/h/ln,
- MSF_2 = 1,250 pc/h/ln,
- MSF_3 = 1,690 pc/h/ln,
- MSF_4 = 2,080 pc/h/ln, and
- MSF_5 = 2,400 pc/h/ln.

Service flow rates, SF_i are estimated by using Equation 11-9.

$$SF_i = MSF_i \times N \times f_{HV} \times f_p$$

where the maximum service flow rates are as cited, N = 4 lanes in each direction, and the driver population factor f_p is 1.00. The heavy vehicle adjustment factor must be determined for 8% trucks and 1% RVs in rolling terrain. From Exhibit 11-10, for rolling terrain, E_T = 2.5 and E_R = 2.0. Then

$$f_{HV} = \frac{1}{1 + 0.08(2.5 - 1) + 0.01(2.0 - 1)} = 0.885$$

Service flow rates may now be computed:

$$SF_1 = 770 \times 4 \times 0.885 \times 1.00 = 2,726 \text{ veh/h}$$

$$SF_2 = 1,250 \times 4 \times 0.885 \times 1.00 = 4,425 \text{ veh/h}$$

$$SF_3 = 1,690 \times 4 \times 0.885 \times 1.00 = 5,983 \text{ veh/h}$$

$$SF_4 = 2,080 \times 4 \times 0.885 \times 1.00 = 7,363 \text{ veh/h}$$

$$SF_5 = 2,400 \times 4 \times 0.885 \times 1.00 = 8,496 \text{ veh/h}$$

Service flow rates are the maximum rates of flow that may exist in the worst 15-min period of the peak hour while the stated LOS is maintained.

Step 5: Compute Service Volumes, *SV*

Equation 11-10 is used to convert service flow rates to service volumes. The conversion multiplies the service flow rates by the PHF to produce maximum hourly volumes that can be accommodated while the given LOS is maintained during the worst 15 min of the hour.

$$SV_i = SF_i \times PHF$$

$$SV_1 = 2,726 \times 0.87 = 2,372 \text{ veh/h}$$

$$SV_2 = 4,425 \times 0.87 = 3,850 \text{ veh/h}$$

$$SV_3 = 5,983 \times 0.87 = 5,205 \text{ veh/h}$$

$$SV_4 = 7,363 \times 0.87 = 6,406 \text{ veh/h}$$

$$SV_5 = 8,496 \times 0.87 = 7,392 \text{ veh/h}$$

AR0073548

Step 6: Compute Daily Service Volumes, *DSV*

Equation 11-1 is used to convert service volumes to daily service volumes. Daily service volumes are the maximum AADTs that can be accommodated while the given LOS is maintained during the worst 15 min of the peak hour in the peak direction of flow.

$$DSV_i = \frac{SV_i}{K \times D}$$

$$DSV_A = \frac{2,372}{0.08 \times 0.60} = 49,417 \text{ veh/day}$$

$$DSV_B = \frac{3,850}{0.08 \times 0.60} = 80,208 \text{ veh/day}$$

$$DSV_C = \frac{5,205}{0.08 \times 0.60} = 108,438 \text{ veh/day}$$

$$DSV_D = \frac{6,406}{0.08 \times 0.60} = 133,458 \text{ veh/day}$$

$$DSV_E = \frac{7,392}{0.08 \times 0.60} = 154,000 \text{ veh/day}$$

Discussion

These results can be conveniently shown in the form of a table, as illustrated in Exhibit 11-22. Given the approximate nature of these computations and the default values used, it is appropriate to round the DSV values to the nearest 100 veh/day, and SF and SV values to the nearest 10 veh/h.

Exhibit 11-22
Service Flow Rates, Service Volumes, and Daily Service Volumes for Example Problem 6

LOS	*SF* (veh/h)	*SV* (veh/h)	*DSV* (veh/day)
A	2,730	2,370	49,400
B	4,430	3,850	80,200
C	5,990	5,210	108,400
D	7,360	6,410	133,500
E	8,500	7,390	154,000

Exhibit 11-22, of course, applies only to the basic freeway segment as described. Should any of the prevailing conditions change, the values in the exhibit would also change. However, for a given segment, forecast demand volumes, whether given as flow rates, hourly volumes, or AADTs, could be compared with the criteria in Exhibit 11-22 to determine the likely LOS immediately. For example, if the 10-year forecast AADT for this segment is 125,000 veh/day, the expected LOS would be D.

APPENDIX A: COMPOSITE GRADES

The composite grade procedure should be used for a series of grades that are 4,000 ft in length and that have a portion of the grade steeper than 4%.

The procedure finds the equivalent single grade that results in the same final truck speed as the series of grades would.

In a basic freeway segment analysis, an overall average grade can be substituted for a series of grades if no single portion of the grade is steeper than 4% or the total length of the grade is less than 4,000 ft. For grades outside these limits (i.e., a portion of the grade is greater than 4% and the total length of the grade is greater than or equal to 4,000 ft), the composite grade procedure presented in this appendix is recommended. The composite grade procedure is used to determine an equivalent grade that will result in the same final speed of trucks as would the series of grades making up the composite.

The acceleration and deceleration curves presented here are for vehicles with an average weight-to-horsepower ratio of 200 lb/hp, heavier than typical trucks found on freeways, which range between 125 lb/hp and 150 lb/hp. This is done in recognition of the fact that heavier trucks will have more of an impact on the traffic stream than lighter trucks.

Exhibit 11-A1 shows typical acceleration (dashed lines) and deceleration (solid lines) performance for a truck with a ratio of 200 lb/hp. The curves are conservative in that they assume a maximum truck speed of 55 mi/h for trucks entering a grade and 60 mi/h for trucks accelerating on a grade.

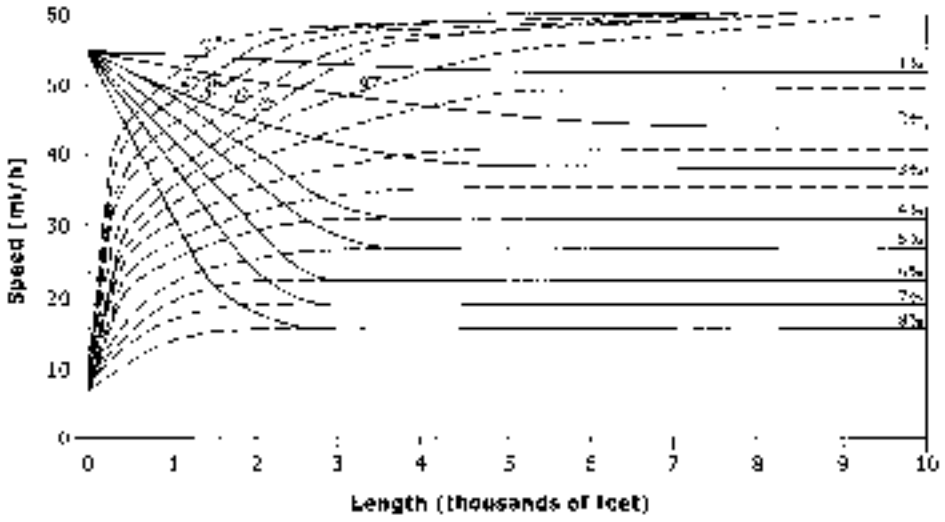

Exhibit 11-A1
Performance Curves for 200 lb/hp Truck

EXAMPLE PROBLEM

An example is provided to illustrate the process involved in determining an equivalent grade for a composite grade on a freeway. The example has two segments, but the procedure is valid for any number of segments. The composite grade is:

- Upgrade of 2% for 5,000 ft, followed by
- Upgrade of 6% for 5,000 ft.

This grade should not be analyzed with an average grade approach, because one portion of the grade is steeper than 4% and the total length of the grade is in

AR0073551

excess of 4,000 ft. As a comparison, application of the average grade approach in this case would yield the following:

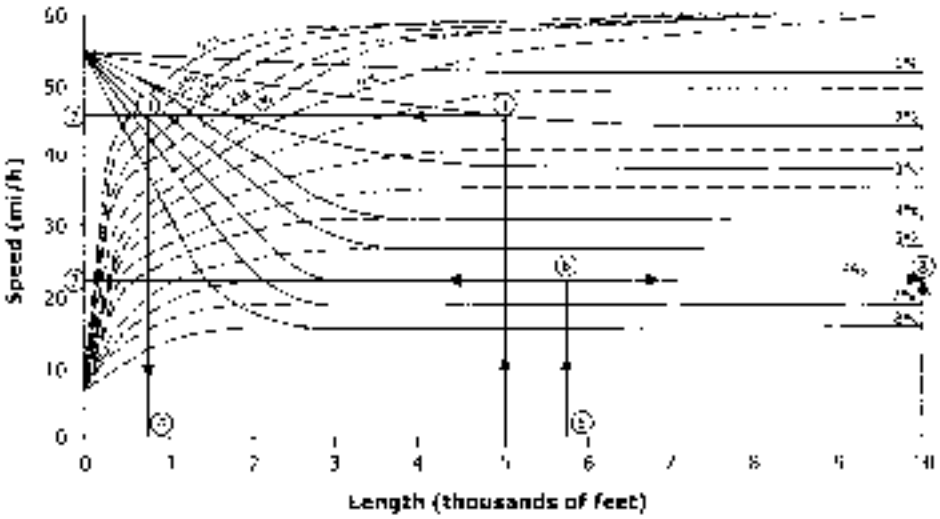
- Total rise along composite: (5,000 × 0.02) + (5,000 × 0.06) = 400 ft.
- Average grade: 400/10,000 = 0.04, or 4%.

With the average grade approach, the composite would be analyzed as if it were a single upgrade of 4%, 10,000 ft (1.89 mi) long.

Exhibit 11-A2 illustrates the recommended solution.

Exhibit 11-A2
Solution Using Composite Grade Procedure

The flat portions of the upgrade curves indicate the truck crawl speed on that grade.



A vertical line is drawn at 5,000 ft to the intersection with the curve for the +2% grade (Point 1). A horizontal line is drawn from the intersection point to the y-axis (Point 2). This procedure indicates that after 5,000 ft of +2% upgrade, trucks will be operating at a speed of approximately 48 mi/h.

This speed is also the speed at which trucks enter the +6% segment of the composite grade. The intersection of the 48 mi/h horizontal line with the curve for the +6% grade (Point 3) is found. A vertical line is dropped from this point to the x-axis (Point 4). This procedure indicates that trucks enter the +6% segment of the composite as if they had already been on the +6% grade for approximately 800 ft. Trucks will travel another 5,000 ft along the +6% grade, starting from Point 4. A vertical line is drawn at a distance of 800 + 5,000 = 5,800 ft (Point 5) to the intersection with the curve for the +6% grade (Point 6). A horizontal line drawn from this point to the y-axis (Point 7) indicates that the speed of trucks at the end of the two-segment composite grade will be approximately 23 mi/h.

The solution point is found as the intersection of a vertical line drawn at 10,000 ft (the total length of the composite grade) and a horizontal line drawn at 23 mi/h. The solution is read as the percent grade on which the solution point lies (Point 8). In this case, the point lies exactly on the curve for the 6% grade. Interpolations between curves are permissible.

In this case, the grade that is equivalent to the composite grade is a single grade of 6%, 10,000 ft (1.89 mi) long. This grade is 2% higher than the 4% average grade. The appropriate equivalent grade is the same percentage as the second

AR0073552

segment of the composite grade because trucks have already reached crawl speed. Once trucks hit crawl speed, it does not matter how far from the beginning of the grade they are; their speed will remain constant.

PROCEDURAL STEPS

The general steps taken in solving for a composite-grade equivalent are summarized as follows:

1. Enter Exhibit 11-A1 with the length of the first segment of the composite grade.
2. Find the truck speed at the end of the first segment of the grade.
3. Find the length along the second segment of the grade that results in the same speed as that found in Step 2.
4. Add the length of the Segment 2 grade to the length determined in Step 3.
5. Repeat Steps 2 through 4 for each subsequent grade segment.
6. Find the intersection of a vertical line drawn at the total length of the composite grade and a horizontal line drawn at the final speed of trucks at the end of the composite grade.
7. Determine the percent of grade for the solution point of Step 6.

DISCUSSION

In the analysis of composite grades, the point of interest is not always at the end of the grade. It is important to identify the point at which the speed of trucks is the lowest because this is where trucks will have the maximum impact on operating conditions. This point may be an intermediate point. If a +3% grade of 1,000 ft is followed by a +4% grade of 2,000 ft, then by a +2% grade of 1,500 ft, the speed of trucks will be slowest at the end of the +4% grade segment. Thus, a composite grade solution would be sought for the first two segments of the grade, with a total grade length of 1,000 + 2,000 = 3,000 ft.

The composite grade procedure is not applicable in all cases, especially if the first segment is a downgrade and the segment length is long or if the segments are too short. In the use of performance curves, cases that cannot be solved with this procedure will become apparent to the analyst because the line will not intersect or the points will fall outside the limits of the curves. In such cases, field measurements of speeds should be used as inputs to the selection of appropriate truck equivalency values.

VOLUME 2: UNINTERRUPTED FLOW
10. Freeway Facilities
11. Basic Freeway Segments
12 Freeway Weaving Segments
13. Freeway Merge and Diverge Segments
14. Multilane Highways
15. Two-Lane Highways

Weaving is generally defined as the crossing of two or more traffic streams traveling in the same direction along a significant length of highway without the aid of traffic control devices (except for guide signs). Thus, weaving segments are formed when merge segments are closely followed by diverge segments. "Closely" implies that there is not sufficient distance between the merge and diverge segments for them to operate independently.

Three geometric characteristics affect a weaving segment's operating characteristics: length, width, and configuration. All have an impact on the critical lane changing activity, which is the unique operating feature of a weaving segment. **Chapter 12, Freeway Weaving Segments,** provides a methodology for analyzing the operation of weaving segments based on these characteristics as well as a segment's free-flow speed (FFS) and the demand flow rates for each movement within a weaving segment (e.g., ramp to freeway or ramp to ramp). This chapter describes how the methodology can be applied to planning, operations, and design applications and provides examples of these applications.

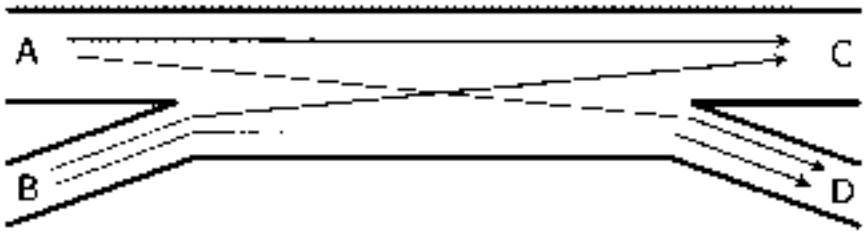
AR0073557

2. WEAVING SEGMENT CHARACTERISTICS

OVERVIEW

Exhibit 12-1 illustrates a freeway weaving segment. On entry and exit roadways, or legs, vehicles traveling from Leg A to Leg D must cross the path of vehicles traveling from Leg B to Leg C. Flows A–D and B–C are, therefore, referred to as *weaving movements*. Flows A–C and B–D may also exist, but as they are not required to cross the path of any other flow, they are referred to as *nonweaving movements*.

Exhibit 12-1
Formation of a Weaving Segment



Traffic in a weaving segment experiences more lane changing maneuvers as drivers must access lanes appropriate to their desired exit leg. Therefore, traffic in a weaving segment is subject to lane-changing turbulence in excess of that normally present on basic freeway segments.

Weaving segments require intense lane-changing maneuvers as drivers must access lanes appropriate to their desired exit leg. Therefore, traffic in a weaving segment is subject to lane-changing turbulence in excess of that normally present on basic freeway segments. This additional turbulence presents operational problems and design requirements, which are addressed by this chapter's methodology.

A weaving segment's geometry affects its operating characteristics.

Three geometric characteristics affect a weaving segment's operating characteristics:

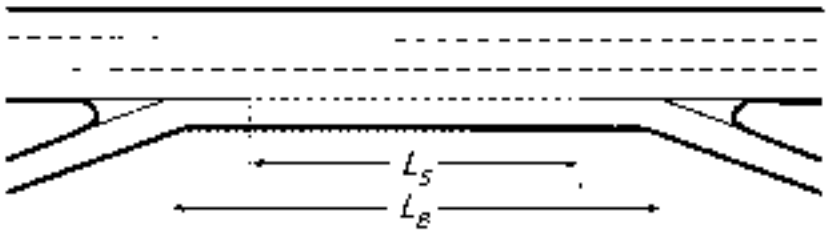
- Length,
- Width, and
- Configuration.

Length is the distance between the merge and diverge that form the weaving segment. *Width* refers to the number of lanes within the weaving segment. *Configuration* is defined by the way entry and exit lanes are aligned. All have an impact on the critical lane-changing activity, which is the unique operating feature of a weaving segment.

LENGTH OF A WEAVING SEGMENT

The two measures of weaving segment length that are relevant to this chapter's methodology are illustrated in Exhibit 12-2.

Exhibit 12-2
Measuring the Length of a Weaving Segment



AR0073558

The lengths illustrated are defined as follows:

- L_s = short length, the distance in feet between the end points of any barrier markings (solid white lines) that prohibit or discourage lane changing.
- L_b = base length, the distance in feet between points at the respective gore areas where the left edge of the ramp-traveled way and the right edge of the freeway-traveled way meet.

Neither of these definitions is the same as those used in previous editions of the *Highway Capacity Manual* (HCM). The definitions used throughout the HCM2000 were historically tied to the specifics of the design of loop ramps in a cloverleaf interchange at a time when most weaving segments were part of such interchanges. Modern weaving segments occur in a wide range of situations and designs, and a more general definition of length is appropriate.

The weaving segment length used in the methodology is defined by the distance between barrier markings. Where no markings exist, the length is defined by the distance between where the far edge of the ramp gore area and the right edge of the freeway-traveled way meet.

This methodology includes several equations that include the length of the weaving segment. In all cases, these equations use the short length L_s. This is not to suggest that lane changing in a weaving segment is restricted to this length. Some lane changing takes place over solid white lines and even painted gore areas. Nevertheless, research has shown that the short length is a better predictor of operating characteristics within the weaving segment than either the base length or the length as defined in HCM2000 and previous editions.

For weaving segments in which no solid white lines are used, the two lengths illustrated in Exhibit 12-2 are the same, that is, $L_s = L_b$. In dealing with future designs in which the details of markings are unknown, a default value should be based on the general marking policy of the operating agency. At the time this methodology was developed, where solid white lines were provided, L_s was equal to 0.77 × L_b on average for the available data.

The estimated speeds and densities, however, apply over the base length L_b. Some evidence also indicates that these speeds and densities may apply to the 500 ft of freeway upstream of the merge and downstream of the diverge because of presegregation of movements in each case.

The weaving segment length strongly influences lane-changing intensity. For any given demand situation, longer segments allow weaving motorists more time and space to execute their lane changes. This reduces the density of lane changing and, therefore, turbulence. Lengthening a weaving segment both increases its capacity and improves its operation (assuming a constant demand).

Under constant demand conditions, making a weaving segment longer increases its capacity and improves its operation.

WIDTH OF A WEAVING SEGMENT

The width of a weaving segment is measured as the number of continuous lanes within the segment, that is, the number of continuous lanes between the entry and exit gore areas. Acceleration or deceleration lanes that extend partially into the weaving segment are not included in this count.

The number of continuous lanes between gore areas within a weaving segment defines its width.

While additional lanes provide more space for both weaving and nonweaving vehicles, they encourage additional optional lane changing activity. Thus, while reducing overall densities, additional lanes can increase lane changing activity and intensity. In most cases, however, the number of lanes in

AR0073559

the weaving segment is controlled by the number of lanes on the entry and exit legs and the intended configuration.

CONFIGURATION OF A WEAVING SEGMENT

Configuration of a weaving segment refers to the way that entry and exit lanes are linked. The configuration determines how many lane changes a weaving driver must make to complete the weaving maneuver successfully. The following sections use a great deal of terminology to describe configurations; this terminology should be clearly understood.

One-Sided and Two-Sided Weaving Segments

One-sided weaving segments require no more than two lane changes to complete a weaving maneuver.

Most weaving segments are one-sided. In general, this means that the ramps defining the entry to and exit from the weaving segment are on the same side of the freeway—either both on the right (most common) or both on the left. The methodology of this chapter was developed for one-sided weaving segments; however, guidelines are given for applying the methodology to two-sided weaving segments.

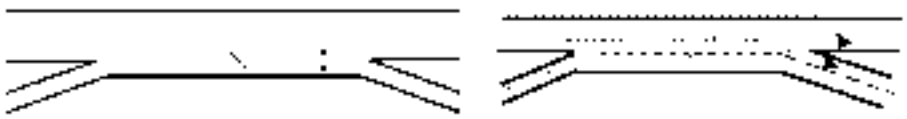
Two-sided weaving segments require three or more lane changes to complete a weaving maneuver or have a single-lane entry ramp closely followed by a single-lane off-ramp on the opposite side of the freeway.

One- and two-sided weaving segments are defined as follows:

- A *one-sided weaving segment* is one in which no weaving maneuvers require more than two lane changes to be completed successfully.
- A *two-sided weaving segment* is one in which at least one weaving maneuver requires three or more lane changes to be completed successfully or at which a single-lane on-ramp is closely followed by a single-lane off-ramp on the opposite side of the freeway.

Exhibit 12-3 illustrates two examples of one-sided weaving segments.

Exhibit 12-3
One-Sided Weaving Segments Illustrated

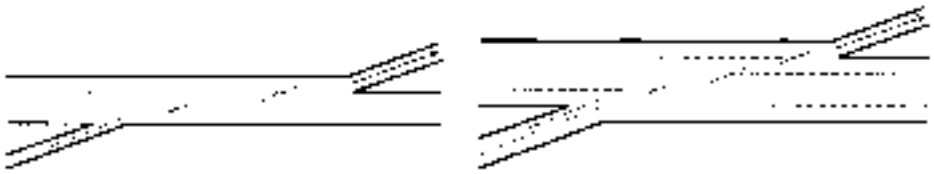


(a) One-Sided Ramp Weave (b) One-Sided Major Weave

Exhibit 12-3(a) shows a typical one-sided weaving segment formed by a one-lane, right-side on-ramp followed closely by a one-lane, right-side off-ramp. The two are connected by a continuous freeway auxiliary lane. Every weaving vehicle must make one lane change as illustrated, and the lane-changing turbulence caused is clearly focused on the right side of the freeway. Exhibit 12-3(b) shows another one-sided weaving segment in which the off ramp has two lanes. One weaving movement (ramp to freeway) requires one lane change. The other (freeway to ramp) can be made without making a lane change. Again, lane changing turbulence is focused on the right side of the freeway.

AR0073560

Exhibit 12-4 Illustrations of examples of two-sided weaving segments



(a) Two-Sided Weave Section with Single Lane Ramps

(b) Two-Sided Weaving Section with Three Lane Changes

Exhibit 12-4
Two-Sided Weaving Segments Illustration

Exhibit 12-4(a) is the most common form of a two-sided weave. A one-lane, right-side on-ramp is closely followed by a one-lane, left-side off-ramp (or vice versa). Although the ramp-to-ramp weaving movement requires only two lane changes, this movement is still classified as a two-sided weave because the geometry of the through movement on the freeway technically qualifies as a weaving flow.

Exhibit 12-4(b) is a less typical case in which one of the ramps has multiple lanes. Because the ramp-to-ramp weaving movement must execute three lane changes, it is also classified as a two-sided weaving segment.

Ramp-Weave Versus Major Weave Segments

Exhibit 12-3 can also be used to illustrate the difference between a ramp-weaving segment and a major weaving segment. Exhibit 12-3(a) shows a typical ramp-weaving segment, formed by a one-lane on ramp closely followed by a one-lane off-ramp, connected by a continuous freeway auxiliary lane. The unique feature of the ramp-weave configuration is that all weaving drivers must execute a lane change across the lane line separating the freeway auxiliary lane from the right lane of the freeway mainline.

One-sided configurations where a continuous auxiliary lane connecting an on ramp to a closely following off ramp are treated as isolated ramp junctions (Chapter 13) and not as weaving segments.

It is important to note that the case of a one-lane on ramp closely followed by a one-lane off-ramp (on the same side of the freeway), but not connected by a continuous freeway auxiliary lane, is not considered to be a weaving configuration. Such cases are treated as isolated merge and diverge segments by using the methodology described in Chapter 13. The distance between the on ramp and the off ramp is not a factor in this determination.

Exhibit 12-3(b) shows a typical major weaving segment. A major weaving segment is formed when three or more entry or exit legs have multiple lanes.

Numerical Measures of Configuration

Three numerical descriptors of a weaving segment characterize its configuration:

- LC_{RF} = minimum number of lane changes that a ramp-to-freeway weaving vehicle must make to complete the ramp-to-freeway movement successfully.
- LC_{FR} = minimum number of lane changes that a freeway-to-ramp weaving vehicle must make to complete the freeway-to-ramp movement successfully.

"Minimum number of lane changes" assumes drivers position themselves when entering the weaving segment to make the least number of lane changes possible.

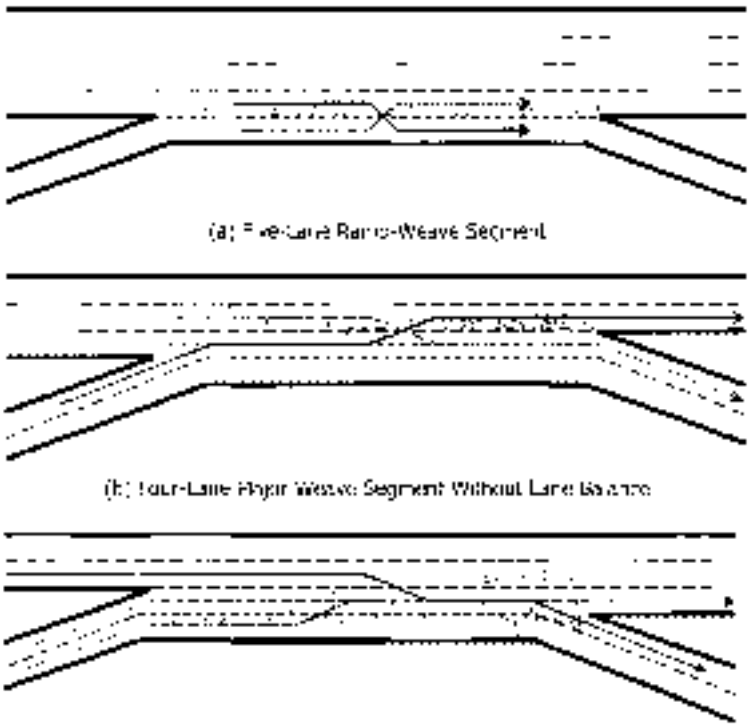
AR0073561

N_{w2} = number of lanes from which a weaving maneuver may be completed with one lane change or no lane changes.

These definitions apply directly to one-sided weaving segments in which the ramp-to-freeway and freeway-to-ramp elements are the weaving movements. Different definitions apply to two-sided weaving segments. Exhibit 12-5 illustrates how these values are determined for one-sided weaving segments.

The values of LC_{RF} and LC_{FR} are found by assuming that every weaving vehicle enters the segment in the lane closest to its desired exit leg and leaves the segment in the lane closest to its entry leg.

Exhibit 12-5
Configuration Parameters Illustrated



(a) Five-Lane Ramp-Weave Segment

(b) Four-Lane Major Weave Segment Without Lane Balance

(c) Four-Lane Major Weave Segment With Lane Balance

Exhibit 12-5(a) is a five-lane ramp-weave configuration. If a weaving driver wishes to exit on the off-ramp and enters the segment on the right-most freeway lane (the lane closest to the off-ramp), the driver must make a single lane change to enter the freeway auxiliary lane and leave via the off-ramp. Thus, for this case, $LC_{FR} = 1$. A weaving driver entering the freeway via the on-ramp has no choice but to enter on the freeway auxiliary lane. The driver must then make a single lane change from the freeway auxiliary lane to the right-most lane of the freeway (the lane closest to the entry leg). Thus, $LC_{RF} = 1$ as well.

Lane balance within a major weave segment provides operational flexibility.

Exhibit 12-5(b) and Exhibit 12-5(c) are both major weaving configurations consisting of four lanes. They differ only in the configuration of their entry and exit gore areas. One has lane balance, while the other does not. Lane balance exists when the number of lanes leaving a diverge segment is one more than the number of lanes entering it.

AR0073562

Exhibit 12-5(b) is not typical. It is used here only to demonstrate the concept of lane balance on a major weaving segment. Five lanes approach the entry to the segment and four lanes leave it; four lanes approach the exit from the segment and four lanes leave it. Because of this configuration, vehicles approaching the exit gore must already be in an appropriate lane for their intended exit leg.

In Exhibit 12-5(b), the ramp-to-freeway weaving movement (right to left) requires at least one lane change. A vehicle can enter the segment on the leftmost ramp lane (the lane closest to the desired exit) and make a single lane change to exit on the rightmost lane of the continuing freeway. LC_{rf} for this case is 1. The freeway-to-ramp weaving movement can be made without any lane changes. A vehicle can enter on the rightmost lane of the freeway and leave on the leftmost lane of the ramp without executing a lane change. For this case, $LC_{fr} = 0$.

The exit junction in Exhibit 12-5(c) has lane balance: four lanes approach the exit from the segment and five lanes leave it. This is a desirable feature that provides some operational flexibility. One lane—in this case, the second lane from the right—splits at the exit. A vehicle approaching in this lane can take either exit leg without making a lane change. This is a useful configuration in cases in which the split of exiting traffic varies over a typical day. The capacity provided by the splitting lane can be used as needed by vehicles destined for either exit leg.

In Exhibit 12-5(c), the ramp-to-freeway movement can be made without a lane change, while the freeway-to-ramp movement requires a single lane change. For this case, $LC_{rf} = 0$ and $LC_{fr} = 1$.

In Exhibit 12-5(a), there are only two lanes from which a weaving movement may be made with no more than one lane change. Weaving vehicles may enter the segment in the freeway auxiliary lane (ramp-to-freeway vehicles) and in the rightmost freeway lane (freeway-to-ramp vehicles) and may execute a weaving maneuver with a single lane change. Although freeway-to-ramp vehicles may enter the segment on the outer freeway lanes, they would have to make more than one lane change to access the off-ramp. Thus, for this case, $N_{wL} = 2$.

In Exhibit 12-5(b), weaving vehicles entering the segment in the leftmost lane of the on-ramp or the rightmost lane of the freeway are forced to merge into a single lane. From this lane, the freeway-to-ramp movement can be made with no lane changes, while the ramp-to-freeway movement requires one lane change. Because the movement-base merges into a single lane, this counts as one lane from which weaving movements can be made with one or fewer lane changes. Freeway-to-ramp vehicles, however, may also enter the segment on the center lane of the freeway and make a single lane change (as shown) to execute their desired maneuver. Thus, for this case, N_{wL} is once again 2.

Lane balance creates more flexibility in Exhibit 12-5(c). Ramp-to-freeway vehicles may enter on either of the two lanes of the on-ramp and complete a weaving maneuver with either one or no lane changes. Freeway-to-ramp vehicles may enter on the rightmost freeway lane and also weave with a single lane change. In this case, $N_{wL} = 3$.

AR0073563

In all one-sided weaving segments, the number of lanes from which weaving maneuvers may be made with one or no lane changes is either two or three. No other values are possible. Segments with $N_{w1} = 3$ generally exist in major weaving segments with lane balance at the exit gore.

Special Case: Two-Sided Weaving Segments

Only the ramp-to-ramp movement is considered to be a weaving flow in a two-sided weaving segment.

The parameters defining the impact of configuration apply only to one-sided weaving segments. In a two-sided weaving segment, neither the ramp-to-freeway nor the freeway-to-ramp movements weave. While the through freeway movement in a two-sided weaving segment might be functionally thought of as weaving, it is the dominant movement in the segment and does not behave as a weaving movement. Thus, in two-sided weaving segments, only the ramp-to-ramp movement is considered to be a weaving flow. This introduces two specific changes to the methodology:

1. Instead of LC_1 and LC_2 being needed to characterize weaving behavior, a value of LC_{12} (the minimum number of lane changes that must be made by a ramp-to-ramp vehicle) is needed. In Exhibit 12-4(a), $LC_{12} = 2$, while in Exhibit 12-4(b), $LC_{12} = 1$.
2. In all cases of two-sided weaving, the value of N_{w1} is set to 0 by definition.

With these two modifications, the methodology outlined for one-sided weaving segments may be applied to two-sided weaving segments as well.

AR0073564

3. METHODOLOGY

The methodology presented in this chapter was developed as part of National Cooperative Highway Research Program (NCHRP) Project 3-77, *Analysis of Freeway Weaving Sections* (1). Elements of this methodology have also been adapted from earlier studies and earlier editions of this manual (2–9).

LIMITATIONS OF THE METHODOLOGY

The methodology of this chapter does not specifically address the following subjects (without modifications by the analyst).

- Special lanes, such as high-occupancy vehicle lanes, within the weaving segment,
- Ramp metering on entrance ramps forming part of the weaving segment,
- Specific operating conditions when oversaturated conditions exist,
- Effects of speed limit enforcement practices on weaving segment operations,
- Effects of intelligent transportation system technologies on weaving segment operations,
- Weaving segments on arterials or other urban streets, including one-way frontage roads,
- Effects of downstream congestion or upstream demand starvation on the analysis segment, or
- Multiple weaving segments.

Multiple weaving segments must be divided into merge, diverge, and simple weaving segments for analysis.

The last subject has been included in previous versions of this manual. Multiple weaving segments must now be divided into appropriate merge, diverge, and simple weaving segments for analysis.

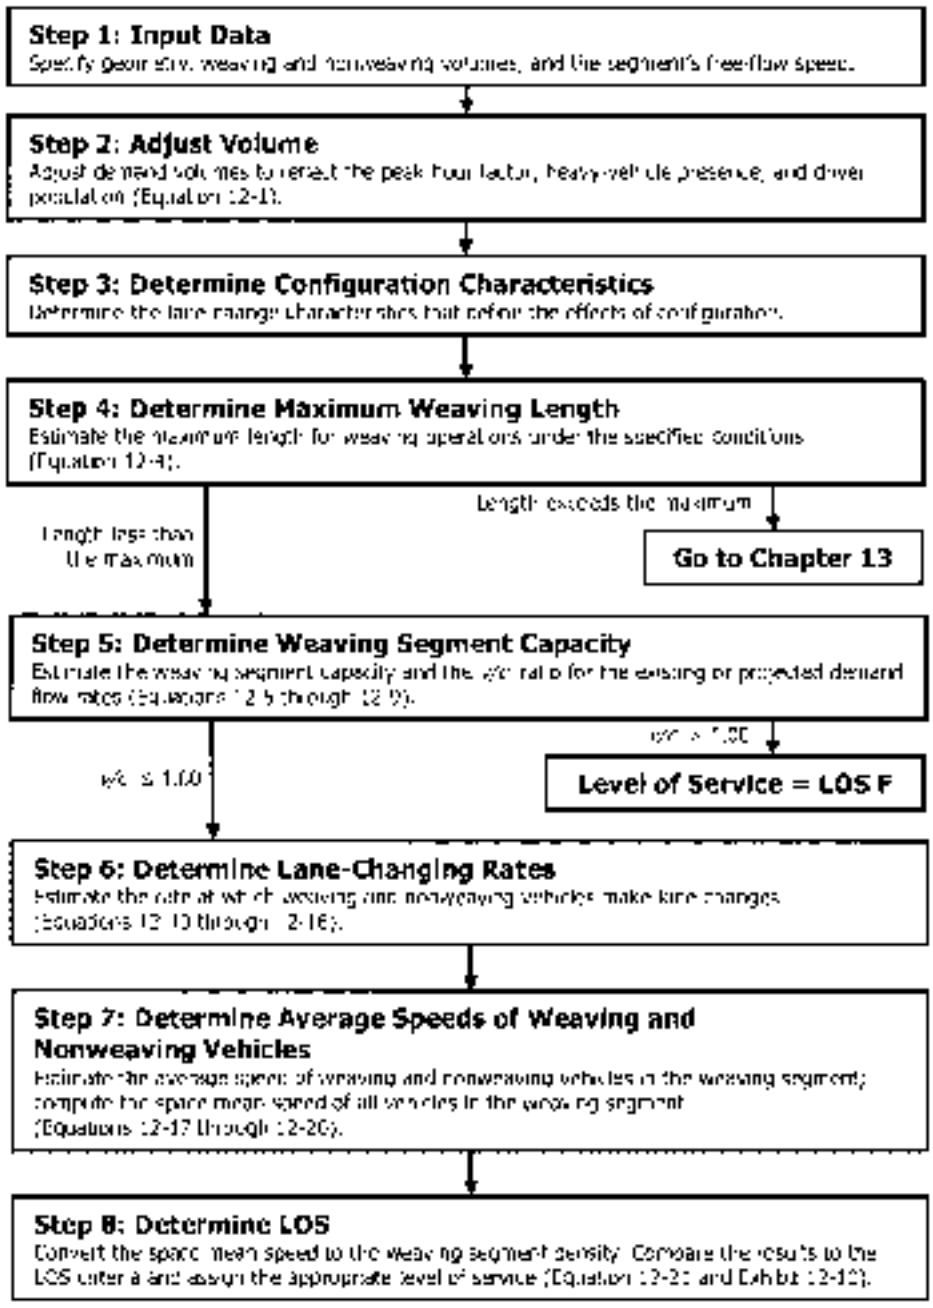
OVERVIEW OF THE METHODOLOGY

Exhibit 12-6 is a flowchart illustrating the basic steps that define the methodology for analyzing freeway weaving segments. The methodology uses several types of predictive algorithms, all of which are based on a mix of theoretical and regression models. These models include the following:

- Models that predict the total rate of lane changing taking place in the weaving segment. This is a direct measure of turbulence in the traffic stream caused by the presence of weaving movements.
- Models to predict the average speed of weaving and nonweaving vehicles in a weaving segment under stable operating conditions, that is, not operating at Level of Service (LOS) F.
- Models to predict the capacity of a weaving segment under both ideal and prevailing conditions.
- A model to estimate the maximum length over which weaving operations can be said to exist.

AR0073565

Exhibit 12-6
Weaving Methodology Flowchart



If the potential weaving segment is longer than the value given in Equation 12-4, it is treated as isolated merging and diverging ramp junctions by using the procedures of Chapter 13.

LOS F exists if a weaving segment's demand exceeds capacity.

PARAMETERS DESCRIBING A WEAVING SEGMENT

Several parameters describing weaving segments have already been introduced and defined. Exhibit 12-7 illustrates all variables that must be specified as input variables and defines those that will be used within or as outputs of the methodology. Some of these apply only to one-sided weaving segments. Exhibit 12-8 lists those variables that are different when applied to two-sided weaving segments.

AR0073566

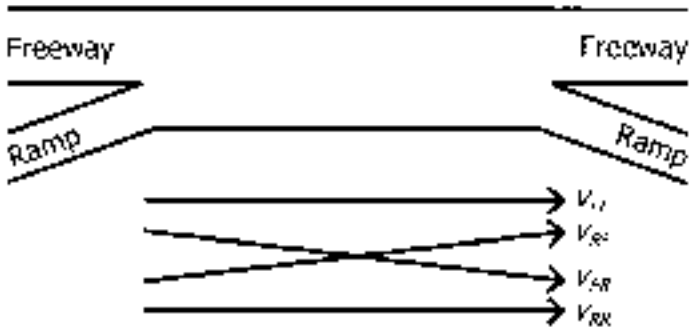


Exhibit 12-7
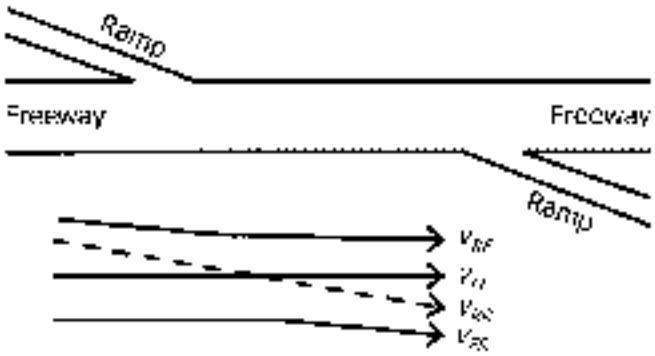
Weaving Variables for One-Sided Weaving Segments

v_{FF} = freeway-to-freeway demand flow rate in the weaving segment in passenger cars per hour (pc/h);
v_{RF} = ramp-to-freeway demand flow rate in the weaving segment (pc/h);
v_{FR} = freeway to ramp demand flow rate in the weaving segment (pc/h);
v_{RR} = ramp-to-ramp demand flow rate in the weaving segment (pc/h);
v_w = weaving demand flow rate in the weaving segment (pc/h): $v_w = v_{RF} + v_{FR}$
v_{NW} = nonweaving demand flow rate in the weaving segment (pc/h): $v_{NW} = v_{FF} + v_{RR}$
v = total demand flow rate in the weaving segment (pc/h): $v = v_{NW} + v_w$
VR = volume ratio: v_w/v;
N = number of lanes within the weaving section;
N_{wl} = number of lanes in which a weaving maneuver may be made with one or no lane changes (see Exhibit 12-5);
S_w = average speed of weaving vehicles within the weaving segment (mi/h);
S_{NW} = average speed of nonweaving vehicles within the weaving segment (mi/h);
S = average speed of all vehicles within the weaving segment (mi/h);
FFS = free flow speed of the weaving segment (mi/h);
D = average density of all vehicles within the weaving segment in passenger cars per mile per lane (pc/mi/ln);
W = weaving intensity factor;
L_S = length of the weaving segment (ft), based on the short length definition of Exhibit 12-2;
LC_{RF} = minimum number of lane changes that must be made by a single weaving vehicle moving from the on-ramp to the freeway (see Exhibit 12-5);
LC_{FR} = minimum number of lane changes that must be made by a single weaving vehicle moving from the freeway to the off-ramp;
LC_{MIN} = minimum rate of lane changing that must exist for all weaving vehicles to complete their weaving maneuvers successfully, in lane changes per hour (lc/h): $LC_{MIN} = 2.5(LC_{RF} + LC_{FR})$;
LC_w = total rate of lane changing by weaving vehicles within the weaving segment (lc/h);
LC_{NW} = total rate of lane changing by nonweaving vehicles within the weaving segment (lc/h);
LC_{ALL} = total rate of lane changing of all vehicles within the weaving segment (lc/h), $LC_{ALL} = LC_w + LC_{NW}$;
ID = interchange density, the number of interchanges within ±3 mi of the center of the subject weaving segment divided by 6, in interchanges per mile (int/mi); and
I_{LC} = lane-changing intensity: $I_{LC} = LC_{ALL}/6$, in lane changes per mile (lc/mi).

AR0073567

Exhibit 12-8
Weaving Variables for a Two-Sided Weaving Segment



The through freeway movement is not considered to be weaving in a two-sided weaving segment.

All variables are defined as in Exhibit 12-7, except for the following variables relating to flow designations and lane-changing variables:

v_w = total weaving demand flow rate within the weaving segment (pc/h), $v_w = v_{bf}$;

v_{nw} = total nonweaving demand flow rate within the weaving segment (pc/h), $v_{nw} = v_{ff} + v_{fr} + v_{rr}$;

LC_{rf} = minimum number of lane changes that must be made by one ramp-to-ramp vehicle to complete a weaving maneuver; and

LC_{av} = minimum rate of lane changing that must occur for all weaving vehicles to complete their weaving maneuvers successfully (pc/h), $LC_{av} = 1.0 \times v_{bf}$.

The principal difference between one-sided and two-sided weaving segments is the relative positioning of the movements within the segment. In a two-sided weaving segment, the ramp-to-freeway and freeway-to-ramp vehicles do not weave. In a one-sided segment, they execute the weaving movements. In a two-sided weaving segment, the ramp-to-ramp vehicles must cross the path of freeway-to-freeway vehicles. Both could be taken to be weaving movements. In reality, the through freeway movement is not weaving in that vehicles do not need to change lanes; nor generally can not shift lane position in response to a desired exit leg.

Thus, in two-sided weaving segments, only the ramp-to-ramp flow is considered to be weaving. The lane-changing parameters reflect this change in the way weaving flows are viewed. Thus, the minimum rate of lane changing that weaving vehicles must maintain to complete all desired weaving maneuvers successfully is also related only to the ramp-to-ramp movement.

The methodology uses demand flow rates for the peak 15 min of passenger cars per hour.

The definitions for flow all refer to *demand flow rate*. This means that for existing cases, the demand should be based on *metered flows*. For future cases, forecasting techniques will generally produce a *demand volume* or *demand flow rate*. All of the methodology's algorithms use demand expressed as flow rates in the peak 15 min of the design (or analysis) hour, in equivalent passenger cars per hour.

COMPUTATIONAL PROCEDURES

Each of the major procedural steps noted in Exhibit 12-6 is discussed in detail in the sections that follow.

AR0073568

Step 1: Input Data

The methodology for weaving segments is structured for operational analysis usage, that is, given a known or specified geometric design and traffic demand characteristics, the methodology is used to estimate the LOS that is expected to exist.

Design and preliminary engineering are generally conducted in terms of comparative analyses of various design proposals. This is a good approach, given that the range of widths, lengths, and configurations in any given case is constrained by a number of factors. Length is constrained by the location of the weaving actions that determine the location of ramp ranges and ramps. Width is constrained by the number of lanes on entry and exit legs and usually involves no more than two choices. Configuration is also the result of the number of lanes on entry and exit legs as well as the number of lanes within the segment. Changing the configuration usually involves adding a lane to one of the entry or exit legs, or both, to create different linkages.

For analysis, the geometry of the weaving segment must be fully defined. This includes the number of lanes, lane widths, shoulder clearances, the details of entry and exit gore area designs (excluding markings), the existence and extent of barrier lines, and the length of the segment. A sketch of the weaving segment should be drawn with all appropriate dimensions shown.

Traffic demands are usually expressed as peak hour volumes under prevailing conditions. If flow rates have been directly observed in the field, the flow rates for the worst 15 min period in the peak hour may be substituted. In this case, the peak hour factor (PHF) is implicitly 1.00.

Step 2: Adjust Volume

All equations in this chapter use flow rates under equivalent ideal conditions as input variables. Thus, demand volumes and flow rates under prevailing conditions must be converted to their ideal equivalents by using Equation 12-1:

$$v_i = \frac{V_i}{PHF \times f_{HV} \times f_p} \qquad \text{Equation 12-1}$$

where

v_i = flow rate under ideal conditions (pc/h);

V_i = hourly volume for flow under prevailing conditions (veh/h);

PHF = peak hour factor;

f_{HV} = adjustment factor for heavy vehicle presence; and

f_p = adjustment factor for driver population (the subscript for the type of flow i can take on the following values:

- w = freeway to freeway,
- o = freeway to ramp,
- i = ramp to freeway,
- r = ramp to ramp).

AR0073569

w = weaving; and

nw = nonweaving.

Factors f_{HV} and f_p are taken from Chapter 11, Basic Freeway Segments.

If flow rates for a 15-min period have been provided as inputs, the PHF is taken to be 1.00 in this computation. If hourly volumes are converted by using a PHF other than 1.00, there is an implicit assumption that all four component flows in the weaving segment peak during the same 15-min period of the hour. This is rarely true in the field, however, such an analysis represents a worst-case scenario.

Once demand flow rates have been established, it may be convenient to construct a weaving diagram similar to those illustrated in Exhibit 12-7 (for one-sided weaving segments) and Exhibit 12-8 (for two-sided weaving segments).

Step 3: Determine Configuration Characteristics

Several key parameters characterize the configuration of a weaving segment. These are descriptive of the segment and will be used as key variables in subsequent steps of the methodology:

LC_{min} = minimum rate at which weaving vehicles must change lanes to complete all weaving maneuvers successfully (veh/h); and

N_{ww} = number of lanes from which weaving maneuvers may be made with either one or no lane changes.

How these values are determined depends on whether the segment under study is a one-sided or two-sided weaving segment.

One-Sided Weaving Segments

The determination of key variables in one-sided weaving segments is illustrated in Exhibit 12-7. In one-sided segments, the two weaving movements are the ramp-to-freeway and freeway-to-ramp flows. As shown in Exhibit 12-7, the following values are established.

LC_{RF} = minimum number of lane changes that must be made by one ramp-to-freeway vehicle to execute the desired maneuver successfully; and

LC_{FR} = minimum number of lane changes that must be made by one freeway-to-ramp vehicle to execute the desired maneuver successfully.

LC_{min} for one-sided weaving segments is given by Equation 12-2:

Equation 12-2

$$LC_{min} = (LC_{RF} \times v_{RF}) + (LC_{FR} \times v_{FR})$$

For one-sided weaving segments, the value of N_{ww} is either 2 or 3. The determination is made by a review of the geometric design and the configuration of the segment, as illustrated in Exhibit 12-5.

Two-Sided Weaving Segments

The determination of key variables in two-sided weaving segments is illustrated in Exhibit 12-8. The unique feature of two-sided weaving segments is that only the ramp-to-ramp flow is functionally weaving. From Exhibit 12-8, the following value is established:

AR0073570

LC_{es} minimum number of lane changes that must be made by one group to merge vehicle to execute the desired maneuver successfully.

LC_{es} for two-sided weaving segments is given by Equation 12-3:

$$LC_{es} = LC_{ef} \times C_{es} \quad \text{Equation 12-3}$$

For two-sided weaving segments, the value of N_{wl} is always 0 by definition.

Step 4: Determine Maximum Weaving Length

The maximum length of a weaving segment, L_{max}, is based on the distance beyond which additional length does not add to capacity.

The concept of maximum length of a weaving segment is critical to the methodology. Strictly defined, *maximum length* is the length at which weaving turbulence no longer has an impact on operations within the segment, or alternatively, on the capacity of the weaving segment.

Unfortunately, depending on the selected definition, these measures can be quite different. Weaving turbulence will have an impact on operations (i.e., weaving and nonweaving vehicle speeds) for distances far in excess of those defined by when the capacity of the segment is no longer affected by weaving.

This methodology uses the second definition (based on the equivalence of capacity). If the operational definition were used, the methodology would produce capacity estimates in excess of those for a similar basic freeway segment, which is illogical. The maximum length of a weaving segment (in feet) is computed from Equation 12-4:

$$L_{max} = \left[5{,}728(1 + VR)^{1.6}\right] - \left[1{,}566N_{ww}\right] \quad \text{Equation 12-4}$$

where L_{max} is the maximum weaving segment length (using the stated length definition) and other variables are as previously defined.

As VR increases, it is expected that the influence of weaving turbulence would extend for longer distances. All values of N_{ww} are either 0 (two-sided weaving segments) or 2 or 3 (one-sided weaving segments). Having more lanes from which easy weaving lane changes can be made reduces turbulence, which in turn reduces the distance over which such turbulence affects segment capacity.

Exhibit 12-9 illustrates the sensitivity of maximum length to both VR and N_{ww}. As expected, VR has a significant impact on maximum length, as does the configuration, as indicated by N_{ww}. While the maximum lengths shown can compute to very high numbers, the highest results are well outside the calibration range of the equation (limited to about 3,800 ft), and many of the situations are improbable. Values of VR on segments with $N_{ww} = 2$ or 3 lanes rarely rise above the range of 0.40 to 0.50. While values of VR above 0.70 are technically feasible on segments with $N_{ww} = 3.0$ lanes, they are rare.

While the extreme values in Exhibit 12-9 are not practical, it is clear that the maximum length of weaving segments can rise to 6,000 ft or more. Furthermore, the maximum length can vary over time, as VR is not a constant throughout every demand period of the day.

AR0073571

Exhibit 12-9
Variation of Weaving Length Versus Weaving Ratio and Number of Weaving Lanes (4)

VR	Number of Weaving Lanes N_{w2} = 2	N_{w3} = 3
0.1	3,540	1,874
0.2	4,546	2,673
0.3	5,584	4,018
0.4	6,682	5,115
0.5	7,826	6,260
0.6	9,019	7,453
0.7	10,256	8,690
0.8	11,538	9,972

If the length of the segment is greater than L_{max}, it should be analyzed as separate merge and diverge components by using the methodology in Chapter 13. Any portion lying outside the influence of the merge and diverge segments is treated as a basic freeway segment.

The value of L_{max} is used to determine whether continued analysis of the configuration as a weaving segment is justified.

- If $L_s \leq L_{max}$, continue to Step 5, or
- If $L_s \geq L_{max}$, analyze the merge and diverge junctions as separate segments by using the methodology in Chapter 13.

If the segment is too long to be considered a weaving segment, then the merge and diverge areas are treated separately. Any distance between the two falling outside the influence areas of the merge and diverge segments would be considered to be a basic freeway segment and would be analyzed accordingly.

Step 5: Determine Weaving Segment Capacity

A weaving segment's capacity is controlled by either (a) the average vehicle density exceeding 43 pc/mi/ln or (b) the weaving demand flow rate exceeding a value that depends on the number of weaving lanes.

The capacity of a weaving segment is controlled by one of two conditions:

- Breakdown of a weaving segment is expected to occur when the average density of all vehicles in the segment reaches 43 pc/mi/ln; or
- Breakdown of a weaving segment is expected to occur when the total weaving demand flow rate exceeds
  - 2,400 pc/h for cases in which N_w = 2 lanes, or
  - 3,500 pc/h for cases in which N_w = 3 lanes.

The first criterion is based on the criteria listed in Chapter 11, Basic Freeway Segments, which state that freeway breakdowns occur at a density of 45 pc/mi/ln. Given the additional turbulence in a weaving segment, breakdown is expected to occur at slightly lower densities.

The second criterion recognizes that there is a practical limit to how many vehicles can mutually cross each other's path without causing serious operational failures. The existence of a third lane from which weaving maneuvers can be made with two or fewer lane changes in effect spreads the impacts of turbulence across segment lanes and allows for higher weaving flows.

For two-sided weaving segments (N_{ww} = 0 lanes), no limiting value on weaving flow rate is proposed. The analysis of two-sided weaving segments is approximate with this methodology, and a density sufficient to cause a breakdown is generally reached at relatively low weaving flow rates.

Weaving Segment Capacity Determined by Density

The capacity of a weaving segment, based on reaching a density of 43 pc/mi/ln, is estimated by using Equation 12-5:

AR0073572

$$c_{ow} = c_{fo} - \left[438.2(1 + VR)^{1.3}\right] - \left[0.0765L_s\right] + \left[119.8N_{wl}\right]$$

Equation 12-5

where

c_{ow} = capacity of the weaving segment under equivalent ideal conditions, per lane (pc/h/ln), and

c_{fo} = capacity of a basic freeway segment with the same FFS as the weaving segment under equivalent ideal conditions, per lane (pc/h/ln).

All other variables are as previously defined.

The model describes the capacity of a weaving segment in terms of the difference between the capacity of a basic freeway segment and the capacity of a weaving segment with the same FFS. Capacity decreases with VR, which is logical. It increases as length and number of weaving lanes N_{wl} increase. These are also logical trends, as both increasing length and a larger number of weaving lanes reduce the intensity of turbulence.

Arithmetically, it is possible to get a result in which c_{ow} is greater than c_{fo}. In practical terms, this will never occur. The maximum length algorithm of Step 4 was found by setting the two values equal. Thus, weaving analyses would only be undertaken in cases in which c_{ow} is less than c_{fo}.

The value of c_{ow} must now be converted to total capacity under prevailing conditions by using Equation 12-6:

$$c_w = c_{ow} N f_{HV} f_p$$

Equation 12-6

where c_w is the capacity of the weaving segment under prevailing conditions in vehicles per hour. As with all capacities, it is stated as a flow rate for a 15-min analysis period.

Weaving Segment Capacity Determined by Weaving Demand Flows

The capacity of a weaving segment, as controlled by the maximum weaving flow rates noted previously, is found from Equation 12-7:

$$c_w = \frac{2{,}400}{VR} \quad \text{for } N_{wl} = 2 \text{ lanes}$$

$$c_w = \frac{3{,}500}{VR} \quad \text{for } N_{wl} = 3 \text{ lanes}$$

Equation 12-7

where c_w is the capacity of all lanes in the weaving segment under ideal conditions in passenger cars per hour, and all other variables are as previously defined. This value must be converted to prevailing conditions by using Equation 12-8:

$$c_w = c_w f_{HV} f_p$$

Equation 12-8

Final Determination of Capacity

The final capacity is the smaller of the two estimates of Equation 12-6 and Equation 12-8. With capacity determined, a v/c ratio for the weaving segment may be computed from Equation 12-9:

AR0073573

Equation 12-9

$$v/c = \frac{v f_{HV} f_p}{c_{iw}}$$

Adjustment factors are used because the total demand flow rate, v, is stated for equivalent ideal conditions, while c_{iw} is stated for prevailing conditions.

Level of Service F

LOS F occurs when demand exceeds capacity

If v/c is greater than 1.00, demand exceeds capacity, and the segment is expected to fail, that is, have a LOS of F. If this occurs, the analysis is terminated, and LOS F is assigned. At LOS F, it is expected that queues will form within the segment, possibly extending upstream beyond the weaving segment itself. Queuing on the on-ramps that are part of the weaving segment would also be expected. Where LOS F is found to exist, the analyst is urged to use the methodology of Chapter 10, Freeway Facilities, to analyze the impacts of this on upstream and downstream segments during the analysis period and over time.

Step 6: Determine Lane-Changing Rates

The equivalent hourly rate at which weaving and nonweaving vehicles make lane changes within the weaving segment is a direct measure of turbulence. It is also a key determinant of speeds and densities within the segment, which ultimately determine the existing or anticipated LOS.

It should be noted that the lane-changing rates estimated are in terms of equivalent *passenger car lane changes*. It is assumed that heavy-vehicle lane changes create more turbulence than passenger-car lane changes.

Three types of lane changes can be made within a weaving segment:

- *Required lane changes made by weaving vehicles.* These lane changes must be made to complete a weaving maneuver and are restricted to the physical area of the weaving segment. In Step 3, the rate at which such lane changes are made by weaving vehicles, LC_{RW}, was determined.
- *Optional lane changes made by weaving vehicles.* These lane changes are not necessary to weave successfully. They involve weaving drivers who choose to enter the weaving segment in the outer lanes of either the freeway or ramp (assuming it has more than one lane), leave the weaving segment in an outer lane, or both. Such drivers make additional lane changes beyond those absolutely required by their weaving maneuver.
- *Optional lane changes made by nonweaving vehicles.* Nonweaving vehicles may also make lane changes within the weaving segment, but neither the configuration nor their desired origin and destination would require such lane changes. Lane changes by nonweaving vehicles are always made because the driver chooses that option.

While LC_{RW} can be computed from the weaving configuration and the demand flow rates, additional optional lane changes made by both weaving and nonweaving vehicles add to turbulence and must be estimated by using regression-based models.

AR0073574

Estimating the Total Lane-Changing Rate for Weaving Vehicles

The model for predicting the total lane-changing rate for weaving vehicles is of the form MLC_{ex} plus an algorithm that predicts the additional optional lane-changing rate. These are combined so that the total lane-changing rate for weaving vehicles, including both required and optional lane changes, is as shown in Equation 12-10:

$$LC_w = LC_{MIN} - 0.39\left[(L_s - 300)^{1.3} N^{1.3} (1 - ID)^{1.3}\right] \quad \text{Equation 12-10}$$

where

LC_w = equivalent hourly rate at which weaving vehicles make lane changes within the weaving segment (l/h);

LC_{MIN} = minimum equivalent hourly rate at which weaving vehicles must make lane changes within the weaving segment to complete all weaving maneuvers successfully (l/h);

L_s = length of the weaving segment, using the short length definition (ft) (300 ft is the maximum value);

N = number of lanes within the weaving segment, and

ID = interchange density (int/mi).

Equation 12-10 has several interesting characteristics. The term $L_s - 300$ implies that for weaving segments of 300 ft (or shorter), weaving vehicles only make necessary lane changes, that is, $LC_w = LC_{MIN}$. While shorter weaving segments would be an aberration, they do occasionally occur. In using Equation 12-10, however, a length of 300 ft is used for all lengths less than or equal to 300 ft.

This model is also unique in that it is the first use of interchange density in a model not involving determination of the FFS. In this edition of the HCM, however, FFS is partially based on total ramp density rather than interchange density. The two measures are, of course, related to the type of interchange involved. A full cloverleaf interchange has four ramps, while a diamond interchange has two ramps. Care must be taken when determining the value of *total ramp density* and *interchange density*, as they are different numbers.

The algorithm uses the term $1 - ID$ because the value of ID may be either more than or less than 1.00, and the power term would not act consistently on the result. In determining interchange density for a weaving segment, a distance of 3 mi upstream and 3 mi downstream of the midpoint of the weaving segment is used. The number of interchanges within the 6-mi range defined above is counted and divided by 6 to determine the interchange density. The subject weaving segment should be counted as one interchange in this computation. For additional discussion of total ramp density, consult Chapter 11.

The basic sensitivities of this model are reasonable. Weaving-vehicle lane changing increases as the length and width of the weaving segment increase. A longer, wider weaving segment simply provides more opportunities for weaving vehicles to execute lane changes. Lane changing also increases as interchange density increases. Higher interchange densities mean that there are more reasons

AR0073575

for drivers to make optional lane changes based upon their entry or exit at a nearby interchange.

Estimating the Lane-Changing Rate for Nonweaving Vehicles

No nonweaving driver must make a lane change within the confines of a weaving segment. All nonweaving vehicle lane changes are, therefore, optional. These are more difficult to predict than weaving lane changes, as the motivation for nonweaving lane changes varies widely and may not always be obvious. Such lane changes may be made to avoid turbulence, to be better positioned for a subsequent maneuver, or simply to achieve a higher average speed.

The research leading to this methodology (*20*) revealed several discontinuities in the lane-changing behavior of nonweaving vehicles within weaving segments. To identify the areas of discontinuity and to develop an estimation model for these areas, it was necessary to define a "nonweaving vehicle index," I_{nw}, as given in Equation 12-11:

Equation 12-11

$$I_{nw} = \frac{I_w \times (1) \times v_{nw}}{10{,}000}$$

This index is a measure of the tendency of conditions to induce unusually large nonweaving vehicle lane-changing rates. Large nonweaving flow rates, high interchange densities, and long weaving lengths seem to produce situations in which nonweaving lane-changing rates are unusually elevated.

Two models are used to predict the rate at which nonweaving vehicles change lanes in weaving segments. The first, Equation 12-12, covers the majority of cases, that is, cases for which normal lane-changing characteristics are expected. This is the case when I_{nw} is less than or equal to 1,300:

Equation 12-12

$$LC_{nw,1} = (0.2069 v_{nw}) - (0.5427 L_s) - (197.6N)$$

where $LC_{nw,1}$ is the rate of lane changing per hour. The equation shows logical trends in that nonweaving lane changes increase with both nonweaving flow rate and segment length. Less expected is that nonweaving lane changing *decreases* with increasing number of lanes. This trend is statistically very strong and likely indicates more propagation of flows in wider weaving segments. Arithmetically, Equation 12-12 can produce a negative result. Thus, the minimum value must be externally set at 0.

The second model applies to a small number of cases in which the combination of high nonweaving demand flow, high interchange density, and long segment length produce exceptionally high nonweaving lane changing rates. Equation 12-13 is used in cases for which I_{nw} is greater than or equal to 1,950.

Equation 12-13

$$LC_{nw,2} = 2{,}135 + 0.223(v_{nw} - 2{,}000)$$

where $LC_{nw,2}$ is the lane changing rate per hour, and all other variables are as previously defined.

Unfortunately, Equation 12-12 and Equation 12-13 are discontinuous and cover discontinuous ranges of I_{nw}. If the nonweaving index is between 1,301 and

AR0073576

1,950, a straight interpolation between the values of LC_{12} and LC_{w2} is used as shown in Equation 12-14.

$$LC_{12a} = LC_{12} - (LC_{12} - LC_{w2})\left(\frac{I_{ww} - 1{,}300}{650}\right) \quad \text{Equation 12-14}$$

where LC_{ww} is the lane-changing rate per hour, and all other variables are as previously defined. Equation 12-14 only works for cases in which LC_{12a} is less than LC_{w2}. In the vast majority of cases, this will be true (unless the weaving length is longer than the maximum length estimated in Step 4). In the rare case when it is not true, LC_{w2} is used.

Equation 12-15 summarizes this in a more precise way:

$$\begin{aligned}
&\text{If } I_{ww} \le 1{,}300: && LC_{12a} = LC_{12} \\
&\text{If } I_{ww} \ge 1{,}950: && LC_{12a} = LC_{w2} \\
&\text{If } 1{,}300 < I_{ww} < 1{,}950: && LC_{12a} = LC_{12} - (LC_{12} - LC_{w2})\left(\frac{I_{ww} - 1{,}300}{650}\right) \\
&\text{If } LC_{12} > LC_{w2}: && LC_{12a} = LC_{w2}
\end{aligned} \quad \text{Equation 12-15}$$

Total Lane-Changing Rate

The total lane-changing rate (LC_{ALL}) of all vehicles in the weaving segment, in lane changes per hour, is computed from Equation 12-16:

$$LC_{ALL} = LC_{12a} + LC_{21} \quad \text{Equation 12-16}$$

Step 7: Determine Average Speeds of Weaving and Nonweaving Vehicles in Weaving Segment

The heart of this methodology is the estimation of the average speeds of weaving and nonweaving vehicles in the weaving segment. These speeds are estimated separately because they are affected by different factors, and they can be significantly different from each other.

The speeds of weaving and nonweaving vehicles will be combined to find a space mean speed of all vehicles in the segment. This will then be converted to a density, which will determine the LOS.

Average Speed of Weaving Vehicles

The algorithm for predicting the average speed of weaving vehicles in a weaving segment may be generally stated as shown in Equation 12-17:

$$S_w = S_{w(MIN)} + \left(\frac{S_{w(MAX)} - S_{w(MIN)}}{1 + W}\right) \quad \text{Equation 12-17}$$

where

S_w = average speed of weaving vehicles within the weaving segment (mi/h),

$S_{w(MIN)}$ = minimum average speed of weaving vehicles expected in a weaving segment (mi/h),

$S_{w(MAX)}$ = maximum average speed of weaving vehicles expected in a weaving segment (mi/h), and

W = weaving intensity factor.

AR0073577

The form of the model is logical and constrains the result to a reasonable range, defined by the minimum and maximum speed expectations. The term $1 + W$ accommodates a weaving intensity factor that can be more or less than 1.0.

For this methodology, the minimum expected speed is taken to be 15 mi/h, and the maximum expected speed is the FFS. As with all analyses, the FFS is best observed in the field, either on the subject facility or a suitable facility. When measured, the FFS should be observed within the weaving segment.

In circumstances that require the FFS to be estimated, the model described in Chapter 11, Basic Freeway Segments, is used. The average speed of weaving vehicles within the weaving segment is estimated by using Equation 12-18 and Equation 12-19.

Equation 12-18

$$S_w = 15 + \frac{(FFS - 15)}{(1 + W)}$$

Equation 12-19

$$W = 0.226\left(\frac{VR \cdot LC_{all}}{L_S}\right)^{0.789}$$

Note that weaving intensity is based on the total lane-changing rate within the weaving segment. More specifically, it is based on the hourly rate of lane changes per foot of weaving length. This might be thought of as a measure of the density of lane changes. In addition, the lane-changing rate itself depends on many demand and physical factors related to the design of the segment.

Average Speed of Nonweaving Vehicles

The average speed of nonweaving vehicles in a weaving segment is estimated by using Equation 12-20:

Equation 12-20

$$S_{nw} = FFS - (0.0072 LC_{all}) - \left(0.0048 \frac{v_{nw}}{N}\right)$$

Equation 12-20 treats nonweaving speed as a reduction from FFS. As would be expected, the speed is reduced as v/N increases. More interesting is the appearance of LC_{all} in the equation. LC_{all} is a measure of minimal weaving turbulence, assuming that weaving vehicles make only necessary lane changes. It depends on both the configuration of the weaving segment and weaving demand flow rates. Thus, nonweaving speeds decrease as weaving turbulence increases.

Average Speed of All Vehicles

The space mean speed of all vehicles in the weaving segment is computed by using Equation 12-21:

Equation 12-21

$$S = \frac{v_w + v_{nw}}{\left(\frac{v_w}{S_w}\right) + \left(\frac{v_{nw}}{S_{nw}}\right)}$$

AR0073578

Step 8: Determine LOS

The LOS in a weaving segment, as in all freeway analyses, is related to the density in the segment. Exhibit 12-10 provides LOS criteria for weaving segments on freeways, collector-distributor (C-D) roadways, and multilane highways. This methodology was developed for freeway weaving segments, although an isolated C-D roadway was included in its development. The methodology may be applied to weaving segments on uninterrupted segments of multilane surface facilities, although its use in such cases is approximate.

LOS can be determined for weaving segments on freeways, multilane highways, and C-D roadways.

Exhibit 12-10
LOS for Weaving Segments

LOS	Density (pc/mi/ln)	
	Freeway Weaving Segments	Weaving Segments on Multilane Highways or C-D Roadways
A	≤ 10	≤ 12
B	>10–20	>12–24
C	>20–28	>24–32
D	>28–35	>32–36
E	>35	>36
F	Demand exceeds capacity	

The boundary between stable and unstable flow—the boundary between levels of service E and F—occurs when the demand flow rate exceeds the capacity of the segment, as described in Step 3. The thresholds for other levels of service were set relative to the criteria for basic freeway segments (or multilane highways). In general, density thresholds in weaving segments are somewhat higher than those for similar basic freeway segments (or multilane highways). It is believed that drivers will tolerate higher densities in an area where lane-changing turbulence is expected than on basic segments.

To apply density criteria, the average speed of all vehicles, computed in Step 7, must be converted to density by using Equation 12-22.

$$D = \frac{\left(\frac{v}{N}\right)_i}{S} \qquad \text{Equation 12-22}$$

where D is density in passenger cars per mile per lane and all other variables are as previously defined.

SPECIAL CASES

Multiple Weaving Segments

When a series of closely spaced merge and diverge areas creates overlapping weaving movements (between different merge–diverge pairs) that share the same segment of a roadway, a multiple weaving segment is created. In earlier editions of the HCM, a specific application of the weaving methodology for two-segment multiple weaving segments was included. While it was a logical extension of the methodology, it did not address cases in which three or more sets of weaving movements overlapped, nor was it well-supported by field data.

AR0073579

Multiple weaving segments should be analyzed as separate merge, diverge, and simple weaving segments, as appropriate.

Multiple weaving segments should be segregated into separate merge, diverge, and simple weaving segments, with each segment appropriately analyzed by using this chapter's methodology or that of Chapter 13, Freeway Merge and Diverge Segments. Chapter 11, Basic Freeway Segments, contains information relative to the process of identifying appropriate segments for analysis.

C-D Roadways

The methodology applies approximately to C-D roadways, but its use may produce an overly negative view of operations.

A common design practice often results in weaving movements that occur on C-D roadways that are part of a freeway interchange. The methodology of this chapter may be approximately applied to such segments. The FFS used must be appropriate to the C-D roadway. It would have to be measured on an existing or similar C-D roadway, as the predictive methodology of FFS given in Chapter 12 does not apply to such roadways. It is less clear that the LOS criteria of Exhibit 12-20 are appropriate. Many C-D roadways operate at lower speeds and higher densities than on basic segments, and the criteria of Exhibit 12-20 may produce an inappropriately negative view of operations on a C-D roadway.

If the measured FFS of a C-D roadway is high (greater than or equal to 50 mi/h), the results of analysis can be expected to be reasonably accurate. At lower FFS values, results would be more approximate.

Multilane Highways

Multilane highway weaving segments may be analyzed with the methodology, except in the words of unsignalized intersections.

Weaving segments may occur on surface multilane highways. As long as such segments are a sufficient distance away from signalized intersections—so that platoon movements are not an issue—the methodology of this chapter may be approximately applied.

Arterial Weaving

No generally accepted analysis methodologies currently exist for arterial weaving movements.

The methodology of this chapter does not apply to weaving segments on arterials. Arterial weaving is strongly affected by the proximity and timing of signals along the arterial. At the present time, there are no generally accepted analytic methodologies for analyzing weaving movements on arterials.

AR0073580

4. APPLICATIONS

The methodology of this chapter is most often used to estimate the capacity and LOS of freeway weaving segments. The steps are most easily applied in the operational analysis mode, that is, all traffic and roadway conditions are specified, and a solution for the capacity (and v/c ratio) is found along with an expected LOS. Other types of analysis, however, are possible.

DEFAULT VALUES

An NCHRP report (10) provides a comprehensive presentation of potential default values for uninterrupted-flow facilities. Default values for freeways are summarized in Chapter 10, Freeway Facilities. These defaults cover the key characteristics of PHF and percentage of heavy vehicles. Recommendations are based on geographical region, population, and time of day. A general freeway default value may be applied to the analysis of weaving segments in the absence of field data or projected conditions.

There are many specific variables related to weaving segments. It is, therefore, virtually impossible to specify default values of such characteristics as length, width, configuration, and balance of weaving and nonweaving flows. Weaving segments are a detail of the freeway design and should therefore be treated only with the specific characteristics of the segment known or projected. Small changes in some of these variables can and do yield significant changes in the analysis results.

TYPES OF ANALYSIS

The methodology of this chapter can be used in three types of analyses: operational, design, and planning and preliminary engineering.

Operational Analysis

The methodology of this chapter is most easily applied in the operational analysis mode. In this application, all weaving demands and geometric characteristics are known, and the output of the analysis is the expected LOS and the capacity of the segment. Secondary outputs include the average speed of component flows, the overall density in the segment, and measures of lane-changing activity.

Design Analysis

Design analysis is best accomplished by iterative operational analyses on a small number of candidate designs.

In design applications, the desired output is the length, width, and configuration of a weaving segment that will sustain a target LOS for given demand flows. This application is best accomplished by iterative operational analyses on a small number of candidate designs.

Generally, there is not a great deal of flexibility in establishing the length and width of a segment, and only limited flexibility in potential configurations. The location of intersecting facilities places logical limitations on the length of the weaving segment. The number of entry and exit lanes on ramps and the freeway itself limits the number of lanes to, at most, two choices. The entry and exit

AR0073581

design of ramps and the freeway facility also produces a configuration that can generally only be altered by adding or subtracting a lane from an entry or exit roadway. Thus, iterative analyses of candidate designs are relatively easy to perform, particularly with the use of LOM replicating software.

Planning and Preliminary Engineering

Planning and preliminary engineering applications generally have the same desired outputs as design applications: the geometric design of a weaving segment that can sustain a target LOS for specified demand flows.

In the planning and preliminary design phase, however, demand flows are generally stated as average annual daily traffic (AADT) that must be converted to directional design hour volumes. A number of variables may be unknown (e.g., PHF and percentage of heavy vehicles); these may be replaced by default values.

Service Flow Rates, Service Volumes, and Daily Service Volumes

This manual defines three sets of values that are related to LOS boundary conditions.

SF_i = service flow rate for LOS i (veh/h),

SV_i = service volume for LOS i (veh/h), and

DSV_i = daily service volume for LOS i (veh/day).

The service flow rate is the maximum rate of flow (for a 15-min interval) that can be accommodated on a segment while maintaining all operational criteria for LOS i under prevailing roadway and traffic conditions. The service volume is the maximum hourly volume that can be accommodated on a segment while maintaining all operational criteria for LOS i during the worst 15 min of the hour under prevailing roadway and traffic conditions. The *daily service volume* is the maximum AADT that can be accommodated on a segment while maintaining all operational criteria for LOS i during the worst 15 min of the peak hour under prevailing roadway and traffic conditions. The service flow rate and service volume are undirectional values, while the daily service volume is a total two-way volume. In the context of a weaving section, the daily service volume is highly approximate, as it is rare that both directions of a freeway have a weaving segment with similar geometry.

In general, service flow rates are initially computed for ideal conditions and are then converted to prevailing conditions by using Equation 12-23 and the appropriate adjustment factors from Chapter 11, Basic Freeway Segments:

Equation 12-23

$$SF = SF_i \times f_{HV} \times f_p$$

where

SF_i = service flow rate under ideal conditions (pc/h),

f_{HV} = adjustment factor for heavy-vehicle presence (Chapter 11), and

f_p = adjustment factor for driver population (Chapter 11).

AR0073582

The methodology of this chapter is used to determine the values of ideal service flow rate (SF_i) for the specific weaving segment under study. The capacity of the segment is equivalent to the ideal service flow rate for LOS E. For other levels of service, the total flow rates required to produce threshold densities (Exhibit 12-10) are found. This is an iterative procedure in which all other characteristics are held constant. Iterative analyses are conducted until the defining densities are produced.

Once the ideal service flow rates are determined, service flow rates under prevailing conditions are computed by using Equation 12-23. These can be converted to hourly service volumes SV by using Equation 12-24. Service volumes can then be converted to daily service volumes DSV by using Equation 12-25.

$$SV_i = SF_i \times PHF \quad \text{Equation 12-24}$$

$$DSV_i = \frac{SV_i}{K \times D} \quad \text{Equation 12-25}$$

where

K = proportion of AADT occurring during the peak hour, and

D = proportion of traffic in the peak direction.

All other variables are as previously defined.

Example Problem 5 illustrates the computation of service flow rates, service volumes, and daily service volumes for a specific weaving segment.

USE OF ALTERNATIVE TOOLS

General guidance for the use of alternative traffic analysis tools for capacity and LOS analysis is provided in Chapter 6, HCM and Alternative Analysis Tools. This section contains specific guidance for the application of alternative tools to the analysis of freeway weaving segments. Additional information on this topic, including supplemental example problems, may be found in Chapter 27, Freeway Weaving, Supplemental, located in Volume 4.

Strengths of the HCM Procedure

The procedures in this chapter were developed from extensive research supported by a significant quantity of field data. They have evolved over a number of years and represent a body of expert consensus. Most alternative tools will not include the level of detail present in this methodology concerning the weaving configuration and balance of weaving demand flows.

Specific strengths of the HCM procedure include:

- Providing capacity estimates for specific weaving configurations as a function of various input parameters, which current simulators do not provide directly (and in some cases may require as an input);
- Considering geometric characteristics (such as lane widths) in more detail than most simulation algorithms;

AR0073583

- Producing a single deterministic estimate of LOS, which is important for some purposes, such as development impact reviews, and
- Generating repeatable results with a small commitment of resources (including calibration) from a precisely documented methodology.

Limitations of the HCM Procedures That Might Be Addressed by Alternative Tools

Weaving segments can be analyzed by using a variety of stochastic and deterministic simulation tools that address freeways. These tools can be very useful in analyzing the extent of congestion when there are features within the simulated facility range and when interaction with other freeway segments and other facilities is present.

The limitations stated earlier in this chapter may be addressed by using available simulation tools. The following conditions, which are beyond the scope of this chapter, are treated explicitly by simulation tools:

- *Managed lanes within the weaving segment.* These lanes are typically modeled explicitly by simulation; for example, when one or more weaving movements are segregated by using pavement markings, signage, physical longitudinal barriers, or some combination of these.
- *Ramp metering on entrance ramps to/within part of the weaving segment.* These features are also modeled explicitly by many tools.
- *Specific operating conditions other than the analyzed conditions exist.* In this case, it is necessary to ensure that both the spatial and the temporal boundaries of the analysis extend beyond the congested operation.
- *Effects of Advanced Transportation System Initiatives on weaving segment operations.* Some intelligent transportation system features such as dynamic message signs are offered by a few simulation tools. Some features are modeled explicitly by simulation; others may be approximated by using assumptions (e.g., by modifying origin–destination demands by time interval).
- *Multiple weaving segments.* Multiple weaving segments were removed from this edition of the manual. They may be addressed to some extent by the procedures given in Chapter 10 for freeway facilities. Complex combinations of weaving segments may be analyzed more effectively by simulation tools, although such analyses might require extensive calibration of origin–destination characteristics.

Because of the interactions between adjacent freeway segments, alternative tools will find their principal application to freeways containing weaving segments at the facility level and not to isolated freeway weaving segments.

Additional Features and Performance Measures Available from Alternative Tools

This chapter provides a methodology for estimating the speed and density in a weaving segment given traffic demands from both the weaving and the nonweaving movements. Capacity estimates and maximum weaving lengths are

AR0073584

also produced. Alternative tools offer additional performance measures including delay, stops, queue lengths, fuel consumption, pollution, and operating costs.

In addition to offering more performance measures, alternative tools can identify specific point problems that could be overlooked in a segment-level analysis.

As with most other procedural chapters in this manual, simulation outputs, especially graphics-based presentations, can provide details on point problems that might otherwise go unnoticed with a macroscopic analysis that yields only segment-level measures. The effect of queuing caused by capacity constraints on the exit ramp of a weaving segment, including difficulty in making the required lane changes, is a good example of a situation that can benefit from the increased insight offered by a microscopic model. An example of the effect of exit ramp queue backup is presented in Chapter 27, Freeway Weaving Supplemental.

Development of HCM-Compatible Performance Measures Using Alternative Tools

When using alternative tools, the analyst must be careful to note the definitions of simulation outputs. The principal measures involved in the performance analysis of weaving segments are speed and delay. These terms are generally defined in the same manner for alternative tools; however, there are subtle differences among tools that often make it difficult to apply HCM criteria directly to the outputs of other tools. Performance measure comparisons are discussed in more detail in Chapter 7, Interpreting HCM and Alternative Tool Results.

Conceptual Differences Between the HCM and Simulation Modeling That Preclude Direct Comparison of Results

Conceptual differences between the HCM and stochastic simulation models make direct comparison difficult for weaving segments. The HCM uses a set of deterministic equations developed and calibrated with field data. Simulation models treat each vehicle as a separate object to be propagated through the system. The physical and behavioral characteristics of drivers and vehicles in the HCM are represented in deterministic equations that compute passenger car equivalences, lane changing rates, maximum weaving lengths, capacity, speed, and density. Simulation models apply the characteristics to each driver and vehicle, and these characteristics produce interactions between vehicles, the sum total of which determines the performance measures for a weaving segment.

Direct comparison of the numerical outputs from the HCM and alternative tools can be misleading.

One good example of the difference between microscopic and macroscopic modeling is how trucks are entered into the models. The HCM uses a conversion factor that increases the demand volumes to reflect the proportion of trucks. Simulation models deal with trucks explicitly by assigning more sluggish characteristics to each of them. The result is that HCM capacities, density, and so forth are expressed in equivalent passenger car units, whereas the corresponding simulation values are represented by actual vehicles.

The HCM methodology estimates the speeds of weaving and nonweaving traffic streams, and on the basis of these estimates it determines the density within the weaving segment. Simulators that provide outputs on a link-by-link basis do not differentiate between weaving and nonweaving movements within

AR0073585

a given line; thus, comparing these (intermediate) results to other tools would be somewhat difficult.

For a given set of inputs, simulation tools should produce answers that are similar to each other and to the HCM. Although most differences should be recognizable through calibration and identification of point problems within a segment, precise numerical agreement is not generally a reasonable expectation.

Sample Calculations Illustrating Alternative Tool Applications

Supplemental computational examples illustrating the use of alternative tools are included in Chapter 27 of Volume 4.

Chapter 27, Freeway Weaving Supplemental, contains three examples that illustrate the application of alternative tools to freeway weaving segments. All of the problems are based on Example Problem 3 presented later in this chapter. Three questions are addressed by using a typical simulation tool:

1. Can the weaving segment capacity be estimated realistically by simulation by varying the demand volumes up to and beyond capacity?
2. How does the demand affect the performance in terms of speed and density in the weaving segment when the default model parameters are used for vehicle and behavioral characteristics?
3. How would the queue backup from a signal at the end of the off-ramp affect the weaving operation?

AR0073586

5. EXAMPLE PROBLEMS

Exhibit 12-11
List of Example Problems

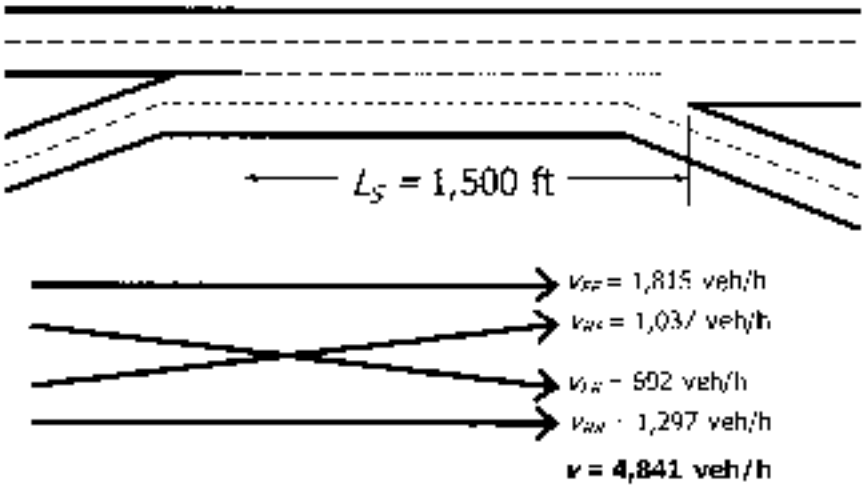
Example Problem	Description	Application
1	LOS of a major weaving segment	Operational Analysis
2	LOS of a ramp-weaving segment	Operational Analysis
3	LOS of a two-sided weaving segment	Operational Analysis
4	Design of a major weaving segment for a desired LOS	Design
5	Service volume table construction	Service Volumes

EXAMPLE PROBLEM 1: LOS OF A MAJOR WEAVING SEGMENT

The Weaving Segment

The subject of this operational analysis is a major weaving segment on an urban freeway, as shown in Exhibit 12-12.

Exhibit 12-12
Major Weaving Segment for Example Problem 1



What is the LOS and capacity of the weaving segment shown in Exhibit 12-12?

The Facts

In addition to the information contained in Exhibit 12-12, the following characteristics of the weaving segment are known:

PHF = 0.91 (for all movements),

Heavy vehicles = 10% trucks, 0% recreational vehicles (RV's) (all movements),

Driver population = regular commuters,

FFS = 65 mi/h,

c_{pl} = 2,350 pc/h/ln (for FFS = 65 mi/h),

f_N = 0.8 ln/mi; and

Terrain = level.

AR0073587

Comments

Chapter 10, Basic Freeway Segments, must be consulted to find appropriate values for the heavy-vehicle adjustment factor f_{HV} and the driver population adjustment factor f_p.

All input parameters have been specified, so default values are not needed. Demand volumes are given in vehicles per hour under prevailing conditions. These must be converted to passenger cars per hour under equivalent ideal conditions for use in equations of the methodology. The length of the segment must be compared with the maximum length for weaving analysis to determine whether the methodology of this chapter is applicable. The capacity of the weaving segment is estimated and compared with the total demand flow to determine whether LOS F exists. Lane-changing rates are estimated to allow speed estimates to be made for weaving and nonweaving flows. An average overall speed and density are computed and compared with the criteria of Exhibit 12-10 to determine LOS.

Step 1: Input Data

All inputs have been specified in Exhibit 12-12 and the Facts section of the problem statement.

Step 2: Adjust Volume

Equation 12-1 is used to convert the four component demand volumes to flow rates under equivalent ideal conditions. Chapter 11 is consulted to obtain a value of E_T (1.5 for level terrain) and f_p (1.00 for regular commuters). The heavy-vehicle adjustment factor is computed as

$$f_{HV} = \frac{1}{1 - P_T(E_T - 1) - P_R(E_R - 1)} = \frac{1}{1 + 0.10(1.5 - 1)} = 0.952$$

Equation 12-1 is now used to convert all demand volumes:

$$v = \frac{V}{PHF \times f_{HV} \times f_p}$$

$$v_{FF} = \frac{1,815}{0.91 \times 0.952 \times 1} = 2,094 \text{ pc/h}$$

$$v_{FR} = \frac{692}{0.91 \times 0.952 \times 1} = 798 \text{ pc/h}$$

$$v_{RF} = \frac{1,037}{0.91 \times 0.952 \times 1} = 1,197 \text{ pc/h}$$

$$v_{RR} = \frac{1,297}{0.91 \times 0.952 \times 1} = 1,497 \text{ pc/h}$$

AR0073588

Then

$$v_{ff} = 798 + 1{,}197 = 1{,}995 \text{ pc/h}$$

$$v_{nw} = 2{,}094 + 1{,}497 = 3{,}591 \text{ pc/h}$$

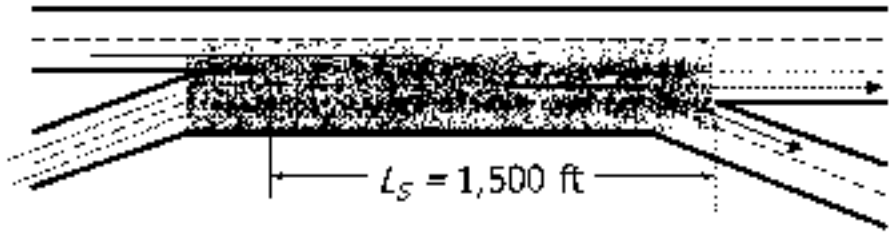
$$v = 1{,}995 + 3{,}591 = 5{,}586 \text{ pc/h}$$

$$VR = \frac{1{,}995}{5{,}586} = 0.357$$

Step 3: Determine Configuration Characteristics

The configuration is examined to determine the values of LC_{ff}, LC_{fr}, and N_{wl}. These determinations are illustrated in Exhibit 12-13. From these values, the minimum number of lane changes by weaving vehicles, LC_{all}, is then computed by using Equation 12-2.

Exhibit 12-13
Determination of Configuration Variables for Example Problem 1



From Exhibit 12-13, it can be seen that ramp-to-freeway vehicles can execute their weaving maneuver without making a lane change (if they so desire). Thus, $LC_{fr} = 0$. Freeway to ramp vehicles must make at least one lane change to complete their desired maneuver. Thus, $LC_{ff} = 1$. If optional lane changes are considered, weaving movements can be accomplished with one or no lane changes from both entering ramp lanes and from the rightmost freeway lane. Thus, $N_{wl} = 3$. Equation 12-2 can now be employed

$$LC_{all} = (LC_{ff} \times v_{ff}) + (LC_{fr} \times v_{fr}) = (0 \times 1197) + (1 \times 798) = 798 \text{ veh/h}$$

Step 4: Determine Maximum Weaving Length

The maximum length over which weaving movements may exist is determined by Equation 12-4. The determination is case specific, and the result is valid only for the case under consideration.

$$L_{max} = [5728(1 + VR)^{1.6}] - [1566 N_{wl}]$$

$$L_{max} = [5728(1 + 0.357)^{1.6}] - [1566 \times 3] = 4{,}639 \text{ ft}$$

As the maximum length is significantly greater than the actual segment length of 1,500 ft, weaving operations do exist, and the analysis may continue with the weaving analysis methodology.

Step 5: Determine Weaving Segment Capacity

Capacity may be controlled by one of two factors: operations reaching a maximum density of 43 pc/mi/ln or by the weaving demand flow rate reaching

AR0073589

3,500 pc/h (for a weaving segment with $N_{wl} = 3$). Equation 12-5 through Equation 12-8 are used to make these determinations.

Capacity Controlled by Density

$$c_{wd} = c_{iq}\left[438.2(1+VR)^{1.3}\right] + \left[0.0765L_s\right] + \left[119.8N_{wl}\right]$$

$$c_{wd} = 2{,}350 - \left[438.2(1+0.357)^{1.3}\right] + \left[0.0765 \times 1{,}500\right] + \left[119.8 \times 3\right]$$

$$c_{wd} = 2{,}110 \text{ pc/h/ln}$$

$$c_w = c_{wd} N f_{HV} f_p = 2{,}110 \times 4 \times 0.952 \times 1 = 8{,}038 \text{ veh/h}$$

Capacity Controlled by Maximum Weaving Flow Rate

$$c_{ww} = \frac{3{,}500}{VR} = \frac{3{,}500}{0.357} = 9{,}800 \text{ pc/h}$$

$$c_w = c_{ww} f_{HV} f_p = 9{,}800 \times 0.952 \times 1 = 9{,}333 \text{ veh/h}$$

Note that the methodology computes the capacity controlled by density in passenger cars per hour per lane, while the capacity controlled by maximum weaving flow rate is computed in passenger cars per hour. After conversion, however, both are in units of vehicles per hour.

The controlling value is the smaller of these, or 8,038 veh/h. As the total demand flow rate is only 5,330 veh/h, the capacity is clearly sufficient, and the situation will not result in LOS F.

Step 6: Determine Lane-Changing Rates

Equation 12-10 through Equation 12-15 are used to estimate the lane-changing rates of weaving and nonweaving vehicles in the weaving segment. In turn, these will be used to estimate weaving and nonweaving vehicle speeds.

Weaving Vehicle Lane-Changing Rate

$$LC_w = LC_{w0} + 0.39\left[(1.\ - 300)^{.25}(N^2)(1+ID)^{.75}\right]$$

$$LC_w = 798 + 0.39\left[(1{,}500 - 300)^{.25}(4^2)(1+0.8)^{.75}\right] = 1{,}144 \text{ lc/h}$$

Nonweaving Vehicle Lane-Changing Rate

$$I_{nw} = \frac{L_s ID v_{nw}}{10{,}000} = \frac{1{,}500 \times 0.8 \times 3{,}591}{10{,}000} = 431 < 1{,}300$$

$$LC_{nw} = (0.206 v_{nw}) + (0.542 L_s) - (192.6N)$$

$$LC_{nw} = (0.206 \times 3{,}591) + (0.542 \times 1{,}500) - (192.6 \times 4) = 782 \text{ lc/h}$$

Total Lane-Changing Rate

$$LC_{all} = LC_w + LC_{nw} = 1{,}144 + 782 = 1{,}926 \text{ lc/h}$$

AR0073590

Step 7: Determine Average Speeds of Weaving and Nonweaving Vehicles

The average speeds of weaving and nonweaving vehicles are computed from Equation 12-28 through Equation 12-30:

$$W = 0.226\left(\frac{LC_{RL}}{t_S}\right)^{0.789} = 0.226\left(\frac{1,926}{1,500}\right)^{0.789} = 0.275$$

Then

$$S_W = 15 - \left(\frac{FFS - 15}{1 + W}\right) = 15 + \left(\frac{65 - 15}{1 + 0.275}\right) = 54.2 \text{ mi/h}$$

and

$$S_{NW} = FFS - (0.0072 LC_{NW}) - \left(0.0048 \frac{v}{N}\right)$$

$$S_{NW} = 65 - (0.0072 \times 798) - \left(0.0048 \times \frac{5,586}{4}\right) = 52.5 \text{ mi/h}$$

Equation 12-31 is now used to compute the average speed of all vehicles in the segment:

$$S = \frac{v_{NW} + v_W}{\left(\frac{v_{NW}}{S_{NW}}\right) + \left(\frac{v_W}{S_W}\right)} = \frac{3,591 + 1,995}{\left(\frac{3,591}{52.5}\right) + \left(\frac{1,995}{54.2}\right)} = 53.1 \text{ mi/h}$$

Step 8: Determine LOS

Equation 12-32 is used to convert the average speed of all vehicles in the segment to an average density:

$$D = \frac{\left(\frac{v}{N}\right)}{S} = \frac{\left(\frac{5,586}{4}\right)}{53.1} = 26.3 \text{ pc/mi/ln}$$

The resulting density of 26.3 pc/mi/ln is compared with the LOS criteria in Exhibit 12-10. The LOS is C, as the density is within the specified range of 20 to 28 pc/h/ln for that level.

Discussion

As indicated by the results, this weaving segment operates at LOS C, with an average speed of 53.1 mi/h for all vehicles. Weaving vehicles travel a bit faster than nonweaving vehicles, primarily because the configuration favors weaving vehicles, allowing as any weaving maneuvers to be made without making a lane change. The demand flow rate of 4,861 veh/h is considerably less than the capacity of the segment, 8,038 veh/h. In other words, demand can grow significantly before reaching the capacity of the segment.

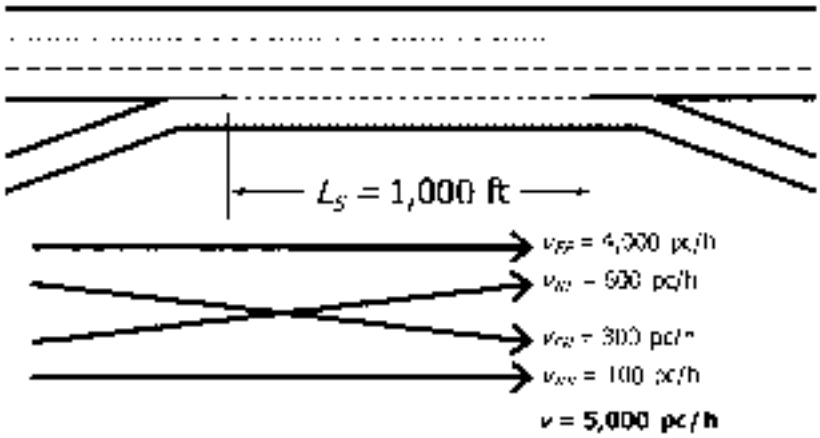
AR0073591

EXAMPLE PROBLEM 2: LOS OF A RAMP-WEAVING SEGMENT

The Weaving Segment

The weaving segment that is the subject of this operational analysis is shown in Exhibit 12-14. It is a typical ramp weave segment.

Exhibit 12-14
Ramp-Weave Segment for Example Problem 2



What is the capacity of the weaving segment of Exhibit 12-14, and at what LOS is it expected to operate with the demand flow rates as shown?

The Facts

In addition to the information given in Exhibit 12-14, the following facts are known about the subject weaving segment:

PHF = 1.00 (demands stated as flow rates);
Heavy vehicles = 6% trucks, 0% RVs (demands given as passenger car equivalents);
Driver population = regular commuters;
FFS = 55 mi/h;
c_{pi} = 2,400 pc/h/ln (for FFS = 75 mi/h);
N = 3 ln/dir; and
Terrain = level.

Comments

Because the demands have been specified as flow rates in passenger cars per hour under equivalent ideal conditions, Chapter 12 does not have to be consulted to obtain appropriate adjustment factors.

Several of the computational steps related to converting demand volumes to flow rates under equivalent ideal conditions are trivial, as demands are already specified in that form. Lane changing, the key issue, will be estimated. The maximum length for weaving operations in this case will be estimated and compared with the actual length of the segment. The capacity of the segment will be estimated and compared with the demand to determine whether LOS F exists. If it does not, exponent flow speeds will be estimated and averaged. A density

AR0073592

will be estimated and compared with the criteria of Exhibit 12-10 to determine the expected LOS.

Step 1: Input Data

All input data are stated in Exhibit 12-14 and the Facts section.

Step 2: Adjust Volume

Because all demands are stated as flow rates in passenger cars per hour under equivalent ideal conditions, no further conversions are necessary. Key volume parameters are as follows:

$$v_{FF} = 4{,}000 \text{ pc/h}$$

$$v_{FR} = 600 \text{ pc/h}$$

$$v_{RF} = 300 \text{ pc/h}$$

$$v_{RR} = 100 \text{ pc/h}$$

$$v_{12} = 600 - 300 = 900 \text{ pc/h}$$

$$v_{34} = 4{,}000 - 100 = 3{,}900 \text{ pc/h}$$

$$v = 4{,}100 + 900 = 5{,}000 \text{ pc/h}$$

$$VR = \frac{900}{5{,}000} = 0.180$$

Step 3: Determine Configuration Characteristics

The configuration is examined to determine the values of LC_{RF}, LC_{FR}, and N_{WL}. These determinations are illustrated in Exhibit 12-15. From these values, the minimum number of lane changes by weaving vehicles (LC_{MIN}) is then computed by using Equation 12-2.

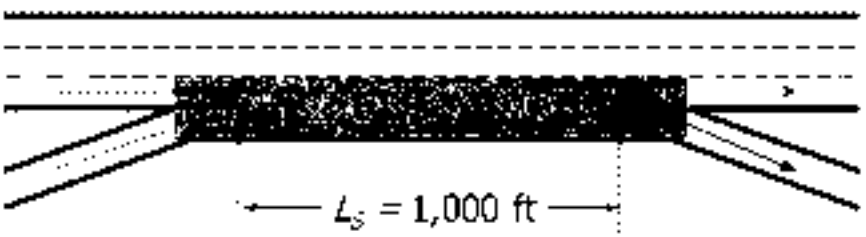


Exhibit 12-15
Configuration Characteristics for Example Problem 2

From Exhibit 12-15, it is clear that all ramp-to-freeway vehicles must make at least one lane change ($LC_{RF} = 1$), and all freeway-to-ramp vehicles must make at least one lane change ($LC_{FR} = 1$). It is also clear that a weaving maneuver can only be completed with a single lane change from the right lane of the freeway or the auxiliary lane ($N_{WL} = 2$). Then, by using Equation 12-2, LC_{MIN} is computed as

$$LC_{MIN} = (LC_{RF} \times v_{RF}) + (LC_{FR} \times v_{FR})$$

$$LC_{MIN} = (1 \times 600) + (1 \times 300) = 900 \text{ lc/h}$$

AR0073593

Step 4: Determine Maximum Weaving Length

The maximum length over which weaving operations may exist for the segment described is found by using Equation 12-4.

$$L_{MAX} = [5{,}728(1 - VR)^{1.6}] - [1{,}566 N_{WL}]$$

$$L_{MAX} = [5{,}728(1 - 0.180)^{1.6}] - [1{,}566 \times 2] = 4{,}333 \text{ ft} > 1{,}000 \text{ ft}$$

As the maximum length for weaving operations significantly exceeds the actual length, this is a weaving segment, and the analysis continues.

Step 5: Determine Weaving Segment Capacity

The capacity of the weaving segment is controlled by one of two limiting factors: density reaches 43 pc/mi/ln or weaving demand reaches 2,400 pc/h for the configuration of Exhibit 12-15.

Capacity Limited by Density

The capacity limited by reaching a density of 43 pc/mi/ln is estimated by using Equation 12-5 and Equation 12-6.

$$c_{WL} = c_{IO} - [438.2(1 + VR)^{1.6}] + [0.0765 L_C] + [119.8 N_{WL}]$$

$$c_{WL} = 2{,}400 - [438.2(1 + 0.180)^{1.6}] + [0.0765 \times 1{,}000] + [119.8 \times 2]$$

$$c_{WL} = 2{,}145 \text{ pc/h/ln}$$

$$c_w = c_{wL} \times N \times f_{HV} \times f_p = 2{,}145 \times 4 \times 1 \times 1 = 8{,}581 \text{ pc/h}$$

Capacity Limited by Weaving Demand Flow

The capacity limited by the weaving demand flow is estimated by using Equation 12-7 and Equation 12-8.

$$c_{IO} = \frac{2{,}400}{VR} = \frac{2{,}400}{0.180} = 13{,}333 \text{ pc/h}$$

$$c_w = c_{IW} \times f_{HV} \times f_p = 13{,}333 \times 1 \times 1 = 13{,}333 \text{ pc/h}$$

The controlling capacity is the smaller value, or 8,581 pc/h. At this point, the value is usually stated as vehicles per hour. In this case, because inputs were already adjusted and were stated in passenger cars per hour, conversions back to vehicles per hour are not possible.

As the capacity is larger than the demand flow rate of 5,000 pc/h, LOS F does not exist, and the analysis continues.

Step 6: Determine Lane-Changing Rates

Equation 12-10 through Equation 12-15 are used to estimate the lane-changing rates of weaving and nonweaving vehicles in the weaving segment. In turn, these will be used to estimate weaving and nonweaving vehicle speeds.

AR0073594

Weaving Vehicle Lane-Changing Rate

$$LC_w = LC_{w0} + 0.39\left[(L_s - 300)^{0.6}(N^{1.2})(1 + ID)^{0.5}\right]$$

$$LC_w = 900 + 0.39\left[(1{,}000 - 300)^{0.6}(4^{1.2})(1 + 1)^{0.5}\right] = 1{,}187 \text{ veh/h}$$

Nonweaving Vehicle Lane-Changing Rate

$$v_{nw} = \frac{(v_{12})(v_{w1})}{10{,}000} = \frac{1{,}000 \times 4{,}100}{10{,}000} = 410 < 1{,}300$$

$$LC_{nw} = (0.206 v_{w1}) + (0.542 L_s) - (192.6 N)$$

$$LC_{nw} = (0.206 \times 4{,}100) + (0.542 \times 1{,}000) - (192.6 \times 4) = 616 \text{ veh/h}$$

Total Lane-Changing Rate

$$LC_{all} = LC_w + LC_{nw} = 1{,}187 + 616 = 1{,}803 \text{ veh/h}$$

Step 7: Determine Average Speeds of Weaving and Nonweaving Vehicles

The average speeds of weaving and nonweaving vehicles are computed from Equation 12-18 through Equation 12-20:

$$W = 0.226\left(\frac{LC_{all}}{L_s}\right)^{0.789} + 0.226\left(\frac{1{,}803}{1{,}000}\right)^{0.789} = 0.360$$

Then

$$S_w = 15 + \frac{(FFS - 15)}{(1 + W)} = 15 + \left[\frac{(75 - 15)}{(1 + 0.360)}\right] = 59.1 \text{ mi/h}$$

and

$$S_{nw} = FFS - (0.0072 LC_{nw}) - \left(0.0048 \frac{v}{N}\right)$$

$$S_{nw} = 75 - (0.0072 \times 900) - \left(0.0048 \times \frac{5{,}000}{4}\right) = 62.5 \text{ mi/h}$$

Equation 12-21 is now used to compute the average speed of all vehicles in the segment:

$$S = \frac{v_{nw} + v_w}{\left(\frac{v_{nw}}{S_{nw}}\right) + \left(\frac{v_w}{S_w}\right)} = \frac{4{,}100 + 900}{\left(\frac{4{,}100}{62.5}\right) + \left(\frac{900}{59.1}\right)} = 61.9 \text{ mi/h}$$

Step 8: Determine LOS

The average density in the weaving segment is estimated by using Equation 12-22:

AR0073595

$$D = \frac{\left(\frac{v}{N}\right)}{S} = \frac{\left(\frac{5{,}810}{4}\right)}{61.9} = 20.2 \text{ pc/mi/ln}$$

From Exhibit 12-10, this density is within the stated boundaries of LOS C (20 to 28 pc/mi/ln). It is, however, very close to the LOS B boundary condition.

Discussion

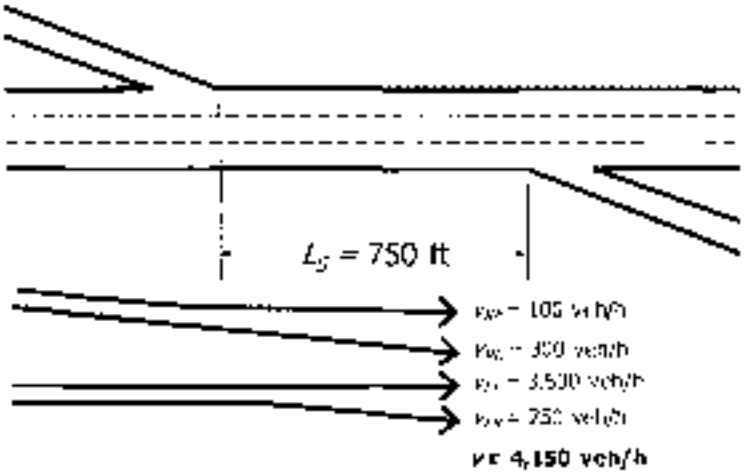
As noted, the segment is operating quite well (LOS C) and is very close to the LOS B boundary. Weaving and nonweaving speeds are relatively high, suggesting a stable flow. The demand flow rate of 5,000 pc/h is well below the capacity of the segment (8,590 pc/h). Weaving vehicles travel somewhat more slowly than nonweaving vehicles, which is typical of ramp-weave segments, where the vast majority of nonweaving vehicles are running from freeway to freeway.

EXAMPLE PROBLEM 3: LOS OF A TWO-SIDED WEAVING SEGMENT

The Weaving Segment

The weaving segment that is the subject of this example problem is shown in Exhibit 12-16.

Exhibit 12-16
Weaving Segment for Example Problem 3



What is the expected LOS and capacity for the weaving segment of Exhibit 12-16?

The Facts

In addition to the information contained in Exhibit 12-16, the following facts concerning the weaving segment are known.

PHF = 0.94 (all movements);
Heavy vehicles = 15% trucks, 0% RVs (all movements);
Driver population = regular commuters;
FFS = 60 mi/h;

AR0073596

c_{fo} = 2,300 pc/h/ln (for FFS = 70 mi/h);

f_N = 2 ln/mi; and

Terrain = rolling.

Comments

Because this example illustrates the analysis of a two-sided weaving segment, several key parameters are redefined.

In a two-sided weaving segment, only the ramp-to-ramp flow is considered to be a weaving flow. While the freeway-to-freeway flow technically weaves with the ramp-to-ramp flow, the operation of freeway-to-freeway vehicles more closely resembles that of nonweaving vehicles. These vehicles generally make very few lane changes as they move through the segment in a freeway lane. The segment is in a busy urban corridor with a high interchange density and a relatively low FFS for the freeway.

Solution steps are the same as in the first two example problems. However, since the segment is a two-sided weaving segment, some of the key values will be computed differently as described in the methodology.

Component demand volumes will be converted to equivalent flow rates in passenger cars per hour under ideal conditions, and key demand parameters will be calculated. A maximum weaving length will be estimated to determine whether a weaving analysis is appropriate. The capacity of the weaving segment will be estimated to determine whether LOS F exists. If not, lane-changing parameters, speeds, density, and LOS will be estimated.

Step 1: Input Data

All information concerning this example problem is given in Exhibit 12-16 and the input section.

Step 2: Adjust Volume

To convert demand volumes to flow rates under equivalent ideal conditions, Chapter 11 must be consulted to obtain the following values:

P_T = 2.5 (for rolling terrain)

f_p = 1.0 (for regular commuters)

Then

$$f_{HV} = \frac{1}{1 + P_T(E_T - 1)} = \frac{1}{1 + 0.15(2.5 - 1)} = 0.816$$

Component demand volumes may now be converted to flow rates under equivalent ideal conditions:

$$v_{FI} = \frac{3,500}{0.94 \times 0.816 \times 1} = 4,561 \text{ pc/h}$$

$$v_{IR} = \frac{250}{0.94 \times 0.816 \times 1} = 326 \text{ pc/h}$$

AR0073597

$$v_{1,2} = \frac{100}{0.94 \times 0.816 \times 1} = 130 \text{ pc/h}$$

$$v_{1,3} = \frac{300}{0.94 \times 0.816 \times 1} = 391 \text{ pc/h}$$

Because this is a two-sided weaving segment, the only weaving flow is the ramp-to-ramp flow. All other flows are treated as nonweaving. Then

v_{nw} = 391 pc/h

v_{ww} = 4,561 + 521 + 130 = 5,017 pc/h

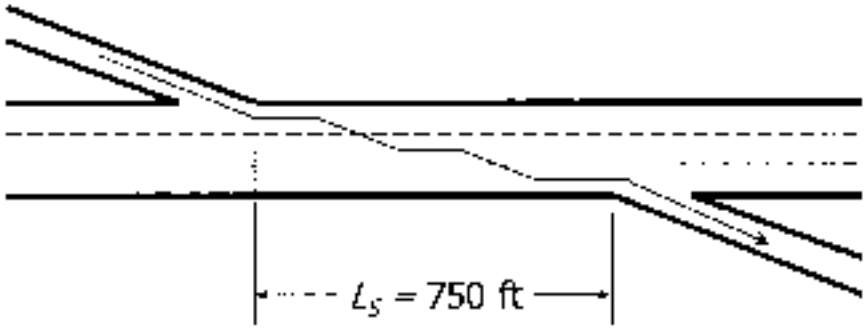
v = 5,017 + 391 = 5,408 pc/h

VR = 391/5,408 = 0.072

Step 3: Determine Configuration Characteristics

The determination of configuration characteristics is also affected by the existence of a two-sided weaving segment. Exhibit 12-17 illustrates the determination of LC_{RR}, the key variable for two-sided weaving segments. For such segments, $N_{WL} = 0$ by definition.

Exhibit 12-17
Configuration Characteristics for Example Problem 3



From Exhibit 12-17, ramp-to-ramp vehicles must make two lane changes to complete their desired weaving maneuver. Then

$$LC_{MIN} = LC_{RR} \times v_{RR} = 2 \times 391 = 782 \text{ lc/h}$$

Step 4: Determine Maximum Weaving Length

The maximum length of a weaving segment for this configuration and demand scenario is estimated by using Equation 12-4:

$$L_{MAX} = [5{,}728(1 + VR)^{1.6}] - [1{,}566 N_{WL}]$$

$$L_{MAX} = [5{,}728(1 + 0.072)^{1.6}] - [1{,}566 * 0] = 6{,}405 \text{ ft} > 750 \text{ ft}$$

In this two-sided configuration, the impacts of weaving on operations could be felt at lengths as long as 6,405 ft. As this is significantly greater than the actual length of 750 ft, this segment clearly operates as a weaving segment and, therefore, the methodology of this chapter should be applied.

AR0073598

Step 5: Determine Weaving Segment Capacity

The capacity of a two-sided weaving segment can only be estimated when a density of 43 pc/h/ln is reached. This estimation is made by using Equation 12-5 and Equation 12-6:

$$c_{wl} = c_{ll} - \left[438.2(1 + VR)^{1.6}\right] - \left[0.0765 L_c\right] + \left[119.8 N_{wl}\right]$$

$$c_{wl} = 2{,}300 - \left[438.2(1 + 0.072)^{1.6}\right] + \left[0.0765 \times 750\right] + \left[119.8 \times 0\right]$$

$$c_{wl} = 1{,}867 \text{ pc/h/ln}$$

$$c_w = c_{wl} \times N \times f_{HV} \times f_p = 1{,}867 \times 3 \times 0.816 \times 1 = 4{,}573 \text{ veh/h} > 4{,}150 \text{ veh/h}$$

Because the capacity of the segment exceeds the demand volume (in vehicles per hour), LOS F is not expected, and the analysis may be continued.

Step 6: Determine Lane-Changing Rates

Equation 12-10 through Equation 12-15 are used to estimate the lane-changing rates of weaving and nonweaving vehicles in the weaving segment. In turn, these will be used to estimate weaving and nonweaving vehicle speeds.

Weaving Vehicle Lane-Changing Rate

$$LC_w = LC_{w0} - 0.39\left[(L_c - 300)^{0.4}(N_w)(1 - ID)^{0.8}\right]$$

$$LC_w = 782 - 0.39\left[(750 - 300)^{0.4}3^1(1 + 2)^{0.8}\right] = 961 \text{ lc/h}$$

Nonweaving Vehicle Lane-Changing Rate

$$L_{NW} = \frac{L_c ID v_{NW}}{10{,}000} = \frac{750 \times 2 \times 5{,}017}{10{,}000} = 753 < 1{,}300$$

$$LC_{NW} = (0.206 v_{w,w}) + (0.542 L_c) - (192.6 N)$$

$$LC_{NW} = (0.206 \times 5{,}017) + (0.542 \times 750) - (192.6 \times 3) = 862 \text{ lc/h}$$

Total Lane Changing Rate

$$LC_{all} = LC_w + LC_{NW} = 961 + 862 = 1{,}823 \text{ lc/h}$$

Step 7: Determine Average Speeds of Weaving and Nonweaving Vehicles

The average speeds of weaving and nonweaving vehicles are computed from Equation 12-18 through Equation 12-20:

$$W = 0.226\left(\frac{LC_{all}}{L_c}\right)^{0.789} - 0.226\left(\frac{1{,}823}{750}\right)^{0.789} + 0.456$$

Then

$$S_w = 15 + \left(\frac{FFS - 15}{1 + W}\right) = 15 + \left(\frac{60 - 15}{1 + 0.456}\right) = 45.9 \text{ mi/h}$$

and

AR0073599

$$S_{ww} = FFS - (0.00726 v_{nonLC}) - \left(0.0048 \frac{v_{LC}}{N}\right)$$

$$S_{ww} = 75 - (0.00726 \times 782) - \left(0.0048 \times \frac{5{,}408}{3}\right) = 45.7 \text{ mi/h}$$

Equation 12-21 is now used to compute the average speed of all vehicles in the segment:

$$S = \frac{v_{nonLC} + v_{LC}}{\left(\frac{v_{nonLC}}{S_{nonLC}}\right) + \left(\frac{v_{LC}}{S_{LC}}\right)} = \frac{5{,}017 + 391}{\left(\frac{5{,}017}{45.7}\right) + \left(\frac{391}{45.9}\right)} = 45.7 \text{ mi/h}$$

Step 8: Determine LOS

The average density in this two-sided weaving segment is estimated by using Equation 12-22:

$$D = \frac{\left(\frac{v}{N}\right)}{S} = \frac{\left(\frac{5{,}408}{3}\right)}{45.7} = 39.4 \text{ pc/mi/ln}$$

From Exhibit 12-16, this density is clearly in LOS E. It is not far from the 43 pc/mi/ln that would likely cause a breakdown.

Discussion

This two-sided weaving segment operates at LOS E, not far from the LOS E/F boundary. The v/c ratio is 4,150/4,575 = 0.91. The major problem is that 948 veh/h crossing the freeway from ramp to ramp creates a great deal of turbulence in the traffic stream and limits capacity. Two-sided weaving segments do not operate well with such large numbers of ramp-to-ramp vehicles. If this were a basic freeway segment, the per lane flow rate of 5,408/3 = 1,803 pc/h/ln would not be considered excessive and would be well within a basic freeway segment's capacity of 2,300 pc/h/ln.

EXAMPLE PROBLEM 4: DESIGN OF A MAJOR WEAVING SEGMENT FOR A DESIRED LOS

The Weaving Segment

A weaving segment is to be designed between two major junctions at which two urban freeways join and then separate as shown in Exhibit 12-18. Entry and exit legs have the numbers of lanes shown. The maximum length of the weaving segment is 1,000 ft, based on the location of the junctions. The FFS of all entry and exit legs is 75 mi/h. All demands are shown as flow rates under equivalent ideal conditions.

AR0073600

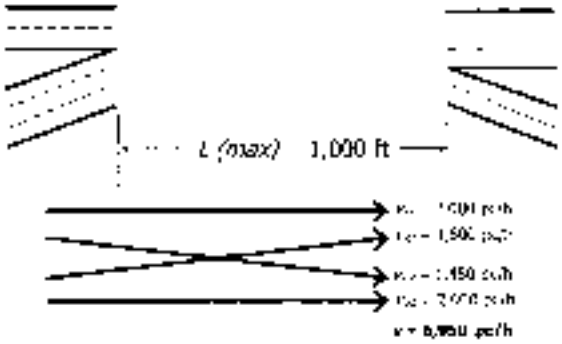


Exhibit 12-18
Weaving Segment for Example Problem 4

What design would be appropriate to deliver LOS C for the demand flow rates shown?

The Facts

In addition to the information contained in Exhibit 12-18, the following facts are known concerning this weaving segment:

PHF = 1.00 (all demands stated as flow rates);
Heavy vehicles = 0% trucks, 0% RVs (all demands in pc/h);
Driver population = regular commuters;
FFS = 75 mi/h;
c_{IL} = 2,400 pc/h/ln (for FFS = 75 mi/h);
f(N) = 1 interchange;
Terrain = level.

Comments

As is the case in any weaving segment design, there are considerable constraints imposed. The problem states that the maximum length is 1,000 ft, an length limited by locational issues for the merge and diverge junctions. It is probably not worth investigating shorter lengths, and the maximum should be executed for all trial designs. The simplest design merely connects entering lanes with exit lanes in a straightforward manner, producing a section of five lanes. A section with four lanes could be considered by merging two lanes into one at the entry gore and separating it into two again at the exit gore. In any event, the design is limited to a section of four or five lanes. No other widths would work without major additions to input and output legs. The configuration cannot be changed without adding a lane to at least one of the entry or exit legs. Thus, the initial trial will be at a length of 1,000 ft, with the five entry lanes connected directly to the five exit lanes, with no changes to the exit or entry lay designs. If this does not produce an acceptable operation, changes will be considered.

While the problem clearly states that all legs are freeways, no feasible configuration produces a two-sided weave section. Thus, to fit within the one-sided analysis methodology, the right-side entry and exit legs will be classified as ramps in the computational analysis.

AR0073601

Step 1: Input Data – Trial 1

All input information is given in Exhibit 12-18 and in the accompanying Facts section for this example problem.

Step 2: Adjust Volume – Trial 1

All demands are already stated as flow rates in passenger cars per hour under equivalent ideal conditions. No further adjustments are needed. Critical demand values are as follows:

$$v_{FF} = 2{,}000 \text{ pc/h}$$

$$v_{14} = 1{,}450 \text{ pc/h}$$

$$v_{24} = 1{,}500 \text{ pc/h}$$

$$v_{12} = 2{,}000 \text{ pc/h}$$

$$v_{23} = 1{,}500 + 1{,}450 = 2{,}950 \text{ pc/h}$$

$$v_{4,34} = 2{,}000 + 2{,}000 = 4{,}000 \text{ pc/h}$$

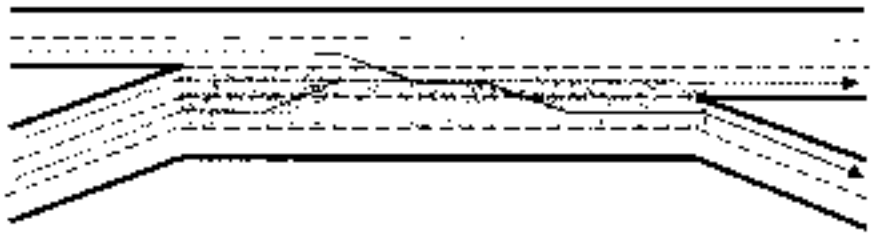
$$v = 2{,}950 + 4{,}000 = 6{,}950 \text{ pc/h}$$

$$VR = \frac{2{,}950}{6{,}950} = 0.424$$

Step 3: Determine Configuration Characteristics – Trial 1

Exhibit 12-19 illustrates the weaving segment formed under the assumed design discussed previously.

Exhibit 12-19
Trial Design 1
for Example Problem 4



The direct connection of entry and exit legs produces a weaving segment in which the ramp-to-freeway movement can be made without a lane change ($LC_{14} = 0$). Freeway-to-ramp vehicles, however, must make two lane changes ($LC_{23} = 2$). If the lane-changing pattern is considered, there are no lanes on the entering freeway leg from which a weaving maneuver can be made with one or no lane changes. Ramp drivers wishing to weave, however, can enter on either of the two left ramp lanes and weave with one or no lane changes. Thus, $N_{w4} = 2$.

By using Equation 12-2, LC_{av} is computed as

$$LC_{av} = (LC_{14} \times v_{14}) + (LC_{24} \times v_{24})$$

$$LC_{av} = (0 \times 1{,}500) + (2 \times 1{,}450) = 2{,}900 \text{ lc/h}$$

AR0073602

Step 4: Determine Maximum Weaving Length – Trial 1

The maximum length of a weaving segment for this configuration and demand scenario is estimated by using Equation 12-6:

$$L_{MAX} = [5{,}728(1 + VR)^{-1}] - [1{,}566N_{ww}]$$

$$L_{MAX} = [5{,}728(1 + 0.424)^{-1}] - [1{,}566 \times 2] = 6{,}950 \text{ ft} > 1{,}000 \text{ ft}$$

As the maximum length is much greater than the actual length of 1,000 ft, it is appropriate to analyze the segment by using this chapter's methodology.

Step 5: Determine Weaving Segment Capacity – Trial 1

The capacity of the weaving segment is controlled by one of two limiting factors: density reaches 43 pc/mi/ln or weaving demand reaches 2,400 pc/h for the configuration of Exhibit 12-19.

Capacity Limited by Density

The capacity limited by reaching a density of 43 pc/mi/ln is estimated by using Equation 12-5 and Equation 12-6:

$$c_{pc,i} = c_{ri} = [438.2(1 + VR)^{1.6}] + [0.0765L_c] + [119.8N_{ww}]$$

$$c_{pc,i} = 2{,}400 = [438.2(1 + 0.424)^{1.6}] + [0.0765 \times 1{,}000] + [119.8 \times 2]$$

$$c_{i,ri} = 1{,}944 \text{ pc/h/ln}$$

$$c_{ri} = c_{i,ri} \times N \times f_{HV} \times f_p = 1{,}944 \times 5 \times 1 \times 1 = 9{,}721 \text{ pc/h}$$

Capacity Limited by Weaving Demand Flow

The capacity limited by the weaving demand flow is estimated by using Equation 12-7 and Equation 12-8:

$$c_{pc,i} = \frac{2{,}400}{VR} = \frac{2{,}400}{0.424} = 5{,}654 \text{ pc/h}$$

$$c_{ri} = c_{i,ri} \times f_{HV} \times f_p = 5{,}654 \times 1 \times 1 = 5{,}654 \text{ pc/h}$$

In this case, the capacity of the segment is limited by the maximum weaving flow rate of 5,654 pc/h, which is smaller than the total demand flow rate of 6,950 pc/h. Thus, this section is expected to operate at LOS F. No further analysis is possible with this methodology.

Discussion – Trial 1

This section would be expected to fail under the proposed design. The critical feature appears to be the configuration. Note that the capacity is limited by the maximum weaving flows that can be sustained, not by a density expected to produce queuing. This is primarily due to the freeway to ramp flow, which must make two lane changes. This number can be reduced to one by adding one lane to the "ramp" at the exit gore area. Not only does this reduce the number of lane changes made by 1,450 freeway-to-ramp vehicles, but it also increases the value of N_w from 2 to 3. In turn, this effectively increases the segment's capacity

AR0073603

(as limited by weaving flow rate) is 3,500/VR = 3,500/0.424 = 8,255 pc/h, which is well in excess of the demand flow rate of 6,950 pc/h. Another analysis (Trial 2) will be conducted by using this approach.

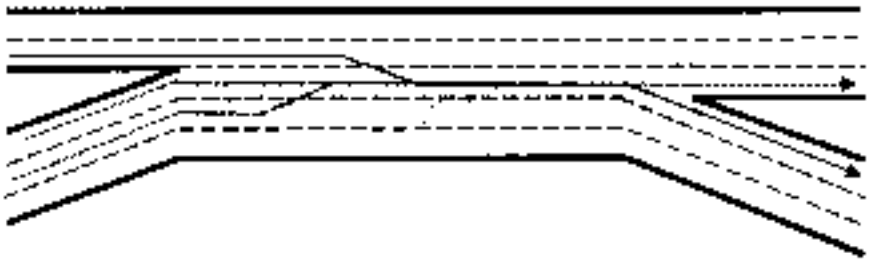
Steps 1 and 2: Input Data and Adjust Volume – Trial 2

Steps 1 and 2 are the same as for Trial 1. They are not repeated here. The new configuration affects the results beginning with Step 3.

Step 3: Determine Configuration Characteristics – Trial 2

Exhibit 12-20 illustrates the new configuration that will result from the changes discussed above. By adding a lane to the exit-ramp leg, the freeway-to-ramp movement can now be completed with only one lane change ($LC_{FR} = 1$). The value of LC_{RF} is not affected and remains 0. The right lane of the freeway-entry leg can also be used by freeway-to-ramp drivers to make a weaving maneuver with a single lane change, increasing N_{wR} to 3.

Exhibit 12-20
Trial Design 2
for Example Problem 4



Then

$$LC_{ALL} = (LC_{FF} \times v_{RF}) + (LC_{FR} \times v_{FF})$$

$$LC_{ALL} = (0 \times 2,580) + (1 \times 2,450) = 2,450 \text{ pc/h}$$

Step 4: Determine Maximum Weaving Length – Trial 2

The maximum length of a weaving segment for this configuration and demand scenario is estimated by using Equation 12-4.

$$L_{MAX} = \left[5,728(1+VR)^{1.6}\right] - \left[1,566N_{WL}\right]$$

$$L_{MAX} = \left[5,728(1+0.424)^{1.6}\right] - \left[1,566 \times 3\right] = 5,393 \text{ ft} > 1,000 \text{ ft}$$

As the maximum length is much greater than the actual length of 1,000 ft, analyzing the segment by using this chapter's methodology is appropriate.

Step 5: Determine Weaving Segment Capacity – Trial 2

The capacity of the weaving segment is controlled by one of two limiting factors: density reaches 43 pc/mi/ln or weaving demand reaches 3,500 pc/h for the configuration of Exhibit 12-20.

Capacity Limited by Density

The capacity limited by reaching a density of 43 pc/mi/ln is estimated by using Equation 12-5 and Equation 12-6.

AR0073604

$$c_{pw} = c_{ir} \left[438.2(1 - VR)^{1.3}\right] + \left[0.0765L_{EL}\right] + \left[119.8N_{WL}\right]$$

$$c_{pw} = 2,400 \left[438.2(1 - 0.424)^{1.3}\right] + \left[0.0765 \times 1,000\right] + \left[119.8 \times 3\right]$$

$$c_{pw} = 2,064 \text{ pc/h/ln}$$

$$c_w = c_{pw} \times N \times f_{HV} \times f_p \quad 2,064 \times 5 \times 1 \times 1 = 10,320 \text{ pc/h}$$

Capacity Limited by Weaving Demand Flow

The capacity limited by the weaving demand flow is estimated by using Equation 12-7 and Equation 12-8:

$$c_{ov} \quad \begin{matrix} 3,500 & 3,500 \\ VR & 0.424 \end{matrix} \quad 8,255 \text{ pc/h}$$

$$c_w = c_{ov} \times f_{HV} \times f_p \quad 8,255 \times 1 \times 1 = 8,255 \text{ pc/h}$$

Once again, the capacity of the segment is limited by the maximum weaving flow rate; the difference is that now the capacity is 8,255 pc/h. This is larger than the total demand flow rate of 6,951 pc/h. Thus, this section is expected to operate without breakdown, and the analysis may continue.

Step 6: Determine Lane-Changing Rates – Trial 2

Equation 12-16 through Equation 12-18 are used to estimate the lane-changing rates of weaving and nonweaving vehicles in the weaving segment. In turn, these will be used to estimate weaving and nonweaving vehicle speeds.

Weaving Vehicle Lane-Changing Rate

$$LC_w = LC_{w0} + 0.39\left[(1 \quad 300)^{0.5}(N^{1})(1 + ID)^{0.5}\right]$$

$$LC_w = 1,450 + 0.39\left[(2,000 - 300)^{0.5}(1)(1 - 1)^{0.5}\right] = 1,899 \text{ lc/h}$$

Nonweaving Vehicle Lane-Changing Rate

$$L_{nw} \quad \frac{L_c ID v_{NW}}{10,000} \quad \frac{1.000 \times 1 \times 4,000}{10,000} \quad 400 < 1,300$$

$$LC_{nw} = (0.206v_{nw}) - (0.542L_c) - (192.6N)$$

$$LC_{nw} = (0.206 \times 4,000) - (0.542 \times 1,000) - (192.6 \times 5) \quad 403 \text{ lc/h}$$

Total Lane-Changing Rate

$$LC_{tot} = LC_w + LC_{nw} = 1,899 + 403 = 2,302 \text{ lc/h}$$

Step 7: Determine Average Speeds of Weaving and Nonweaving Vehicles – Trial 2

The average speeds of weaving and nonweaving vehicles are computed from Equation 12-18 through Equation 12-20.

AR0073605

$$W = 0.226\left(\frac{LC_{ww}}{L_w}\right)^{0.536} = 0.226\left(\frac{2{,}302}{1{,}000}\right)^{0.536} = 0.436$$

Then

$$S_a = 15 - \left(\frac{FFS - 15}{1 + W}\right) = 75 - \left(\frac{75 - 15}{1 + 0.436}\right) = 56.8 \text{ mi/h}$$

and

$$S_{NW} = FFS - (0.0072 LC_{NW}) - \left(0.0048 \frac{v}{N}\right)$$

$$S_{NW} = 75 - (0.0072 \times 1{,}450) - \left(0.0048 \frac{6{,}950}{5}\right) = 57.9 \text{ mi/h}$$

Equation 12-21 is now used to compute the average speed of all vehicles in the segment.

$$S = \frac{v_{NW} + v_W}{\left(\frac{v_{NW}}{S_{NW}}\right) + \left(\frac{v_W}{S_W}\right)} = \frac{4{,}000 + 2{,}950}{\left(\frac{4{,}000}{57.9}\right) + \left(\frac{2{,}950}{56.8}\right)} = 57.4 \text{ mi/h}$$

Step 8: Determine the Level of Service – Trial 2

The average density in the weaving segment is estimated by using Equation 12-22.

$$D = \frac{v}{S} = \frac{6{,}950}{57.4} = 121.2 \text{ pc/mi/ln}$$

From Exhibit 12-10, this density is within the stated boundaries of LOS C (120 to 158 pc/mi/ln). As the design target was LOS C, the second trial design is acceptable.

Discussion – Trial 2

The relatively small change in the configuration makes all the difference in this design. LOS C can be achieved by adding a lane to the right-most leg, without it the section fails due to excessive weaving turbulence. If the extra lane is not needed on the departing freeway leg, it would be dropped somewhere downstream, perhaps as part of the next interchange. The extra lane would have to be carried for several thousand feet to be effective. An added lane generally will not be fully utilized by drivers if they are aware that it will be immediately dropped.

EXAMPLE PROBLEM 5: CONSTRUCTING A SERVICE VOLUME TABLE FOR A WEAVING SEGMENT

This example shows how a table of service flow rates or service volumes or both can be constructed for a weaving section with certain specified characteristics. The methodology of this chapter does not directly yield service

AR0073606

flow rates or service volumes, but they can be developed by using spreadsheets or more sophisticated computer programs.

The key issue is the definition of the threshold values for the various levels of service. For weaving sections on freeways, levels of service are defined as limiting densities as follows:

LOS	Maximum Density (pc/mi/ln)
A	10
B	20
C	28
D	35

By definition, the service flow rate at LOS E is the capacity of the weaving section, which may or may not be keyed to a density.

Before the construction of such a table is illustrated, several key definitions should be reviewed.

- *Service flow rate (under ideal conditions):* The maximum rate of flow under equivalent ideal conditions that can be sustained while maintaining the designated LOS (*SFI*, passenger cars per hour).
- *Service flow rate under prevailing conditions:* The maximum rate of flow under prevailing conditions that can be sustained while maintaining the designated LOS (*SF*, vehicles per hour).
- *Service volume:* The maximum hourly volume under prevailing conditions that can be sustained while maintaining the designated LOS in the worst 15 min of the hour (*SV*, vehicles per hour).
- *Daily service volume:* The maximum AADT under prevailing conditions that can be sustained while maintaining the designated LOS in the worst 15 min of the peak hour (*DSV*, vehicles per day).

Note that flow rates are for a 15-min period, often a peak 15 min within the analysis hour, or the peak hour. These values are related as follows.

$$SF_i = SFI_i \times f_{HV} \times f_p$$

$$SV_i = SF_i \times PHF$$

$$DSV_i = \frac{SV_i}{K D}$$

This chapter's methodology estimates both the capacity and the density expected in a weaving segment of given geometric and demand characteristics. Consequently, the approach to generating values of *SFI* is straightforward: for any given situation, keep increasing the input flow rates until the boundary density for the LOS is reached; the input flow rate is the *SFI* for that situation and LOS. This obviously involves many iterations. A spreadsheet can be programmed to do this, either semiautomatically with manual input of demands, or fully automatically, with the spreadsheet automatically generating solutions until a density match is found. The latter method is not very efficient and involves a typical spreadsheet program running for several hours. A program could, of course, be written to automate the entire process.

AR0073607

An Example

While all of the computations cannot be shown, demonstration results for a specific case can be illustrated. A service volume table is desired for a weaving section with the following characteristics:

- One-sided major weaving section
- Demand splits as follows:
  - v_1 = 65% of v
  - v_{12} = 15% of v
  - v_{21} = 12% of v
  - v_{22} = 8% of v
- Trucks = 10%, RVs = 0%
- Level terrain
- PHF = 0.93
- f_p = 1.00
- w = 12 ft/mi
- FFS = 65 mi/h

For these characteristics, a service volume table can be constructed for a range of lengths and widths and for configurations in which N_{wl} is 2 and 3. For illustrative purposes, lengths of 500, 1,000, 1,500, 2,000, and 2,500 ft and widths of three, four, or five lanes will be used. In a major weaving section, one weaving flow does not have to make a lane change. For the purposes of this example, it is assumed that the ramp-to-freeway movement has this characteristic. The freeway-to-ramp movement would require one or two lane changes, on the basis of the value of N_{wl}.

First Computations

Initial computations will be aimed at establishing values of SF_i for the situations described. A spreadsheet will be constructed in which the first column is the flow rate to be tested (in passenger cars per hour under ideal conditions), and the last column produces a density. Each line will be iterated manually (in this case) until each threshold density value is reached. Intermediate columns will be programmed to produce the intermediate results needed to get to this result. Because maximum length and capacity are decided at intermediate points, the applicable results will be manually entered before continuing. Such a procedure is less difficult than it seems once the basic computations are programmed. Manual iteration using the input flow rate is very efficient, as the operator will observe how fast the results are converging to the desired threshold and will change the inputs accordingly.

The results of a first computation are shown in Exhibit 12-21. They represent service flow rates under ideal conditions, SF_i. Consistent with the HCM's results presentation guidelines (Chapter 7, Interpreting HCM and Alternative Tool Results), all hourly service flow rates and volumes in the following exhibits have

AR0073608

been rounded down to the nearest 100 passenger cars or vehicles for presentation.

Exhibit 12-21
Service Flow Rates Under Ideal Conditions (SF_I) for Example Problem 5 (pc/h)

LOS	Length of Weaving Section (ft)

AR0073614

1. INTRODUCTION

Freeway merge and diverge segments occur primarily at on-ramp and off-ramp junctions with the freeway mainline. They can also occur at major merge or diverge points where mainline roadways join or separate.

Freeway merge and diverge segments include ramp junctions and points where mainline roadways join or separate.

A ramp is a dedicated roadway providing a connection between two highway facilities. On freeways, all movements onto and off of the freeway are made at ramp junctions—designed to permit relatively high-speed merging and diverging maneuvers while limiting the disruption to the main traffic stream. Some ramps on freeways connect to collector–distributor (C-D) roadways, which in turn provide a junction with the freeway mainline. Ramps may appear on multilane highways, two-lane highways, arterials, and urban streets, but such facilities may also use signalized and unsignalized intersections at such junctions.

The procedures in Chapter 13, **Freeway Merge and Diverge Segments**, focus on ramp–freeway junctions, but guidance is also provided to allow approximate use of such procedures on multilane highways and on C-D roadways.

This chapter provides guidance for using the procedures on multilane highways and C-D roadways.

RAMP COMPONENTS

A ramp consists of three elements: the ramp roadway and two junctions. Junctions vary greatly in design and control features but generally fit into one of these categories:

- Ramp–freeway junctions (or a junction with a C-D roadway or multilane highway segment), or
- Ramp–street junctions.

When a ramp connects one freeway to another, the ramp consists of two ramp–freeway junctions and the ramp roadway. When a ramp connects a freeway to a surface facility, it generally consists of a ramp–freeway junction, the ramp roadway, and a ramp–street junction. When a ramp connection to a surface facility (such as a multilane highway) or a C-D roadway is designed for high-speed merging or diverging without control, it may be classified as a ramp–freeway junction for the purpose of analysis.

Ramps to multilane highways and C-D roadways that are designed for high-speed merging or diverging may be classified as ramp–freeway junctions for analysis purposes.

Ramp–street junctions may be uncontrolled, stop-controlled, yield-controlled, or signalized. Analysis of ramp–street junctions is not detailed in this chapter; rather, it is discussed in Chapter 22, Interchange Ramp Terminals. Note, however, that an off-ramp–street junction, particularly if signalized, can result in queuing on the ramp roadway that can influence operations at the ramp–freeway junction and even mainline freeway conditions. Mainline operations can also be affected by platoon gaps created by ramp–street intersection control.

See Chapter 22 for a discussion of ramp–street junctions.

Ramp queuing from a junction of an off-ramp and street can influence the operation of the ramp–freeway junction and the upstream freeway.

The geometric characteristics of ramp–freeway junctions vary. The length and type (parallel, taper) of acceleration or deceleration lane(s), the free-flow speed (FFS) of both the ramp and the freeway in the vicinity of the ramp, proximity of other ramps, and other elements all affect merging and diverging operations.

AR0073615

CLASSIFICATION OF RAMPS

Ramps and ramp–freeway junctions may occur in a wide variety of configurations. Some of the key characteristics of ramps and ramp junctions are summarized below:

- Ramp–freeway junctions that accommodate merging maneuvers are classified as *on-ramps*. Those that accommodate diverging maneuvers are classified as *off-ramps*. Where the junctions accommodate the merging of two major facilities, they are classified as *major merge* junctions. Where they accommodate the divergence of two major roadways, they are classified as *major diverge* junctions.
- The majority of ramps are right-hand ramps. Some, however, join with the left lane(s) of the freeway and are classified as left-hand ramps.
- Ramp roadways may have one or two lanes. At on ramp freeway junctions, most two lane ramp roadways merge into a single lane before merging with the freeway. In this case, the junction is classified as a one-lane ramp–freeway junction on the basis of the methodology of this chapter. In other cases, a two-lane ramp–freeway merge exists, and a special analysis model is used (see this chapter's Special Cases section).
- For two-lane off-ramps, a single lane may exist at the ramp–freeway diverge, with the roadway widening to two lanes after the diverge. As with on-ramps, such cases are classified as one-lane ramp–freeway junctions on the basis of this chapter's methodology. Two lane off ramp roadways, however, often have two lanes at the diverge point as well. These are treated by using a special model (see this chapter's Special Cases section).
- Ramp–freeway merge and diverge operations are affected by the size of the freeway segment (or one direction).
- Ramp–freeway merge and diverge operations may be affected by the proximity of adjacent ramps and the flow rates on those ramps.

Left-hand ramps are considered as special cases later in the chapter.

Merge and diverge segments with two lanes at the point of merge or diverge are considered as special cases later in this chapter.

The number of combinations of these characteristics that can occur is very large. For any analyses, all of these (and other) characteristics must be specified if meaningful results are to be obtained.

RAMP AND RAMP JUNCTION ANALYSIS BOUNDARIES

Ramps and ramp junctions do not operate independently of the roadways they connect. Thus, operating conditions on the main roadways can affect operations on the ramp and ramp junctions, and vice versa. In particular, a breakdown (Level of Service (LOS) F) at a ramp–freeway junction may have serious effects on the freeway upstream or downstream of the junction. These effects can influence freeway operations for miles or the worst cases.

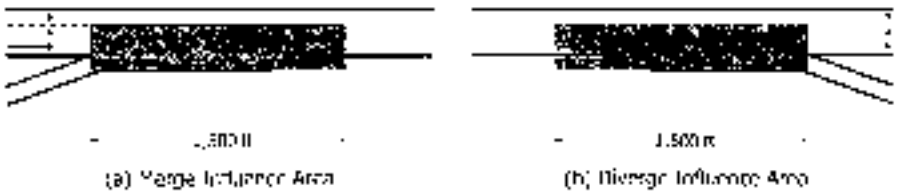
With understated conditions, the operational impacts of ramp–freeway junctions occur within a 1,500-ft-long influence area.

For most stable operations, however, studies (*1*) have shown that the operational impacts of ramp–freeway junctions are more localized. Thus, the methodology presented in this chapter predicts the operating characteristics within a defined ramp influence area. For right-hand on ramps, the ramp influence area includes the acceleration lane(s) and Lanes 1 and 2 of the freeway

AR0073616

mainline (rightmost and second rightmost) for a distance of 1,500 ft downstream of the merge point. For right-hand off-ramps, the ramp influence area includes the deceleration lane(s) and Lanes 1 and 2 of the freeway for a distance of 1,500 ft upstream of the diverge point. Exhibit 13-1 illustrates the definition of ramp influence areas. For left-hand ramps, the two leftmost lanes of the freeway are affected.

The influence area includes the acceleration/deceleration lane and the right two lanes of the freeway (left two lanes for left-hand ramps).



(a) Merge Influence Area (b) Diverge Influence Area

Exhibit 13-1
Ramp Influence Areas Illustrated

RAMP–FREEWAY JUNCTION OPERATIONAL CONDITIONS

Ramp–freeway junctions create turbulence in the merging or diverging traffic stream. In general, the turbulence is the result of high lane-changing rates.

The action of individual merging vehicles entering the Lane 1 traffic stream creates turbulence in the vicinity of the ramp. Approaching freeway vehicles move toward the left to avoid the turbulence. Thus, the ramp influence area experiences a higher rate of lane changing than is normally present on ramp-free portions of freeway.

Ramp influence areas experience higher rates of lane changing than normally occur on basic freeway segments.

At off-ramps, the basic maneuver is a diverge—a single traffic stream separating into two streams. Exiting vehicles must occupy the lane(s) adjacent to the off-ramp (Lane 1 for a single-lane right-hand off-ramp). Thus, as the off-ramp is approached, vehicles leaving the freeway must move to the right. This causes other freeway vehicles to redistribute as they move left to avoid the turbulence of the immediate diverge area. Again, the ramp influence area has a higher rate of lane changing than is normally present on ramp-free portions of freeway.

Vehicle interactions are dynamic in ramp influence areas. Approaching freeway through vehicles will move left as long as there is capacity to do so. Whereas the intensity of ramp flow influences the behavior of through freeway vehicles, general freeway congestion can also act to limit ramp flow, causing diversion to other interchanges or routes.

Exhibit 13-1 and the accompanying discussion relate to single-lane right-hand ramps. For two-lane right-hand ramps, the characteristics are basically the same, except that two acceleration or deceleration lanes may be present. For left-hand ramps, merging and diverging obviously take place on the left side of the freeway. This chapter's methodology is based on right-hand ramps, but modifications allowing the application of the methodology to consider left-hand ramps are presented in the Special Cases section of this chapter.

BASE CONDITIONS

The base conditions for the methodology presented in this chapter are the same as for other types of freeway segments:

Base conditions for merge and diverge segments are the same as for other types of freeway segments.

AR0073617

- No heavy vehicles,
- 12-ft lanes,
- Adequate lateral clearances (≥6 ft), and
- Road users familiar with the facility (i.e., $f_p = 1.00$).

LOS CRITERIA FOR MERGE AND DIVERGE SEGMENTS

LOS A–E is defined in terms of density. LOS F exists when demand exceeds capacity.

Merge/diverge segment LOS is defined in terms of density for all cases of stable operation (LOS A–E). LOS F exists when the freeway demand exceeds the capacity of the upstream (diverge) or downstream (merge) freeway segment, or when the off-ramp demand exceeds the off-ramp capacity.

At LOS A, unrestricted operations exist, and the density is low enough to permit smooth merging or diverging with very little turbulence in the traffic stream. At LOS B, merging and diverging maneuvers become noticeable to through drivers, and minimal turbulence occurs. At LOS C, speed within the ramp influence area begins to decline as turbulence levels become much more noticeable. Both ramp and freeway vehicles begin to adjust their speeds to accomplish smooth transitions. At LOS D, turbulence levels in the influence area become intrusive, and virtually all vehicles slow to accommodate merging or diverging maneuvers. Some ramp queues may exist at heavily used on-ramps, but freeway operation remains stable. LOS E represents operating conditions approaching or at capacity. Small changes in demand or disruptions within the traffic stream can cause extensive ramp and freeway queues to form.

LOS F defines operating conditions within queues that form on both the ramp and the freeway mainline when capacity is exceeded by demand. For on-ramps, LOS F exists when the total demand flow rate from the upstream freeway segment and the on-ramp exceeds the capacity of the downstream freeway segment. For off-ramps, LOS F exists when the total demand flow rate on the approaching upstream freeway segment exceeds the capacity of the upstream freeway segment. LOS F also occurs when the off-ramp demand exceeds the capacity of the off-ramp.

Exhibit 13-2 summarizes the LOS criteria for freeway merge and diverge segments. These criteria apply to all ramp–freeway junctions and may also be applied to auxiliary merges and diverges; high-speed, uncontrolled merge or diverge ramps on multilane highway sections; and merges and diverges on freeway C-D roadways. LOS is not defined for ramp roadways, while the LOS of a ramp–street junction is defined in Chapter 22, Interchange Ramp Terminals.

Exhibit 13-2
LOS Criteria for Freeway Merge and Diverge Segments

LOS	Density (pc/mi/ln)	Comments
A	≤10	Unrestricted operations
B	>10–20	Merging and diverging maneuvers noticeable to drivers
C	>20–28	Influence area speeds begin to decline
D	>28–35	Influence area turbulence becomes intrusive
E	>35	Turbulence felt by virtually all drivers
F	Demand exceeds capacity	Ramp and freeway queues form

AR0073618

REQUIRED INPUT DATA

The analysis of a ramp–freeway junction requires details concerning the junction under analysis and adjacent upstream and downstream ramps, in addition to the data required for a typical freeway analysis.

Data Describing the Freeway

The following information concerning the freeway mainline is needed to conduct an analysis:

1. FFS: 55–75 mi/h;
2. Number of mainline freeway lanes: 2–5;
3. Terrain: level, rolling, or mountainous, or percent grade and length;
4. Heavy vehicle presence: percent trucks and buses, percent recreational vehicles (RVs);
5. Demand flow rate immediately upstream of the ramp–freeway junction;
6. Peak hour factor: up to 1.00; and
7. Driver population factor: 0.85–1.00.

FFS is best measured in the field but can be estimated by using the methodology for basic freeway segments or multilane highways, as applicable.

The freeway FFS is best measured in the field. If a field measurement is not available, one may be estimated by using the methodology for basic freeway segments presented in Chapter 12, Basic Freeway Segments. To use this methodology, information on lane widths, lateral clearances, number of lanes, and total ramp density is required. If the ramp junction is located on a multilane highway or C-D roadway, the FFS range is somewhat lower (45–60 mi/h) and can be estimated by using the methodology in Chapter 14, Multilane Highways, if no field measurements are available. The methodology can be applied to facilities with any FFS. Its use with multilane highways or C-D roadways must be considered approximate, however, since it was not calibrated with data from these types of facilities.

Where the ramp–freeway junction is on a specific grade, the length of the grade is measured from its beginning to the point of the ramp junction.

The driver population factor is generally 1.00, unless the demand consists primarily of drivers who are not regular users of the facility. In such cases, an appropriate value should be based on field observations at the location under study or at similar nearby locations.

Data Describing the Ramp–Freeway Junction

The following information concerning the ramp–freeway junction is needed to conduct an analysis:

1. Type of ramp: on-ramp, off-ramp, major merge, major diverge;
2. Side of junction: right-hand, left-hand;
3. Number of lanes on ramp roadway: 1 lane, 2 lanes;
4. Number of ramp lanes at ramp–freeway junction: 1 lane, 2 lanes;
5. Length of acceleration/deceleration lane(s);
6. FFS of the ramp roadway: 25–50 mi/h.

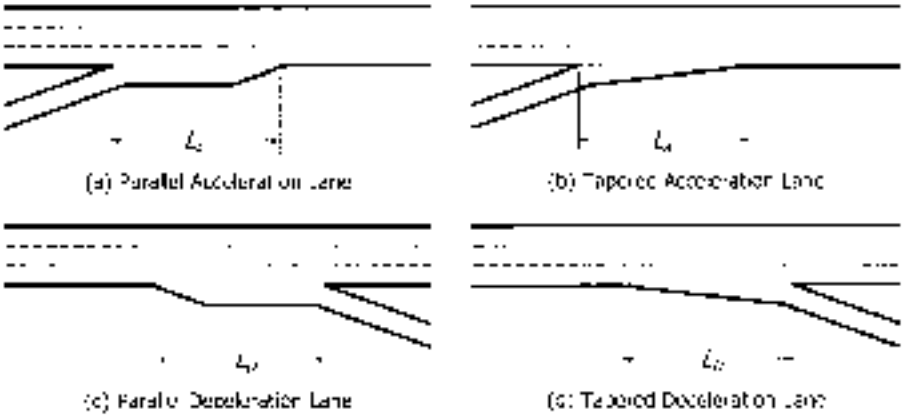
AR0073619

7. Ramp terrain: level, rolling, or mountainous, or percent grade, length;
8. Demand flow rate on ramp;
9. Heavy vehicle presence: percent trucks and buses, percent RVs;
10. Peak hour factor: up to 1.00;
11. Driver population factor: 0.85 - 1.00; and
12. For adjacent upstream or downstream ramps:
    a. Upstream or downstream distance to the merge/diverge under study,
    b. Demand flow rate on the upstream or downstream ramp, and
    c. Peak hour factor and heavy vehicle percentages for the upstream or downstream ramp.

The length of the acceleration or deceleration lane includes the tapered portion of the ramp.

The length of the acceleration or deceleration lane includes the tapered portion of the ramp. Exhibit 13-3 illustrates lengths for both parallel and tapered ramp designs.

Exhibit 13-3
Measuring the Length of Acceleration and Deceleration Lanes



Source: *Traffic Engineering*, 3rd edition [2].

Length of Analysis Period

The analysis period for any freeway analysis, including ramp junctions, is generally the peak 15-min period within the peak hour. Any 15-min period can be analyzed, however.

AR0073620

2. METHODOLOGY

SCOPE OF THE METHODOLOGY

This chapter focuses on the operation of ramp–freeway junctions. The procedures may be applied in an approximate manner to completely uncontrolled ramp terminals on other types of facilities, such as multilane highways, two-lane highways, and freeway C–D roadways that are part of interchanges.

This chapter's procedures can be used to identify likely congestion at ramp–freeway junctions (LOS F) and to analyze undersaturated operations (LOS A–E) at ramp–freeway junctions. Chapter 10, Freeway Facilities, provides procedures for a more detailed analysis of oversaturated flow and congested conditions along a freeway section, including weaving, merge and diverge, and basic freeway segments.

The procedures in this chapter result primarily from studies conducted under National Cooperative Highway Research Program Project 3-33 (7, 8). Some special applications resulted from adaptations of procedures developed in the 1970's (3). American Association of State Highway and Transportation Officials policies (4) contain additional material on the geometric design and design criteria for ramps.

LIMITATIONS OF THE METHODOLOGY

The methodology in this chapter does not take into account, nor is it applicable to (without modification by the analyst), cases involving

- Special lanes, such as high-occupancy vehicle (HOV) lanes, as ramp entry lanes;
- Ramp metering; or
- Intelligent transportation system features.

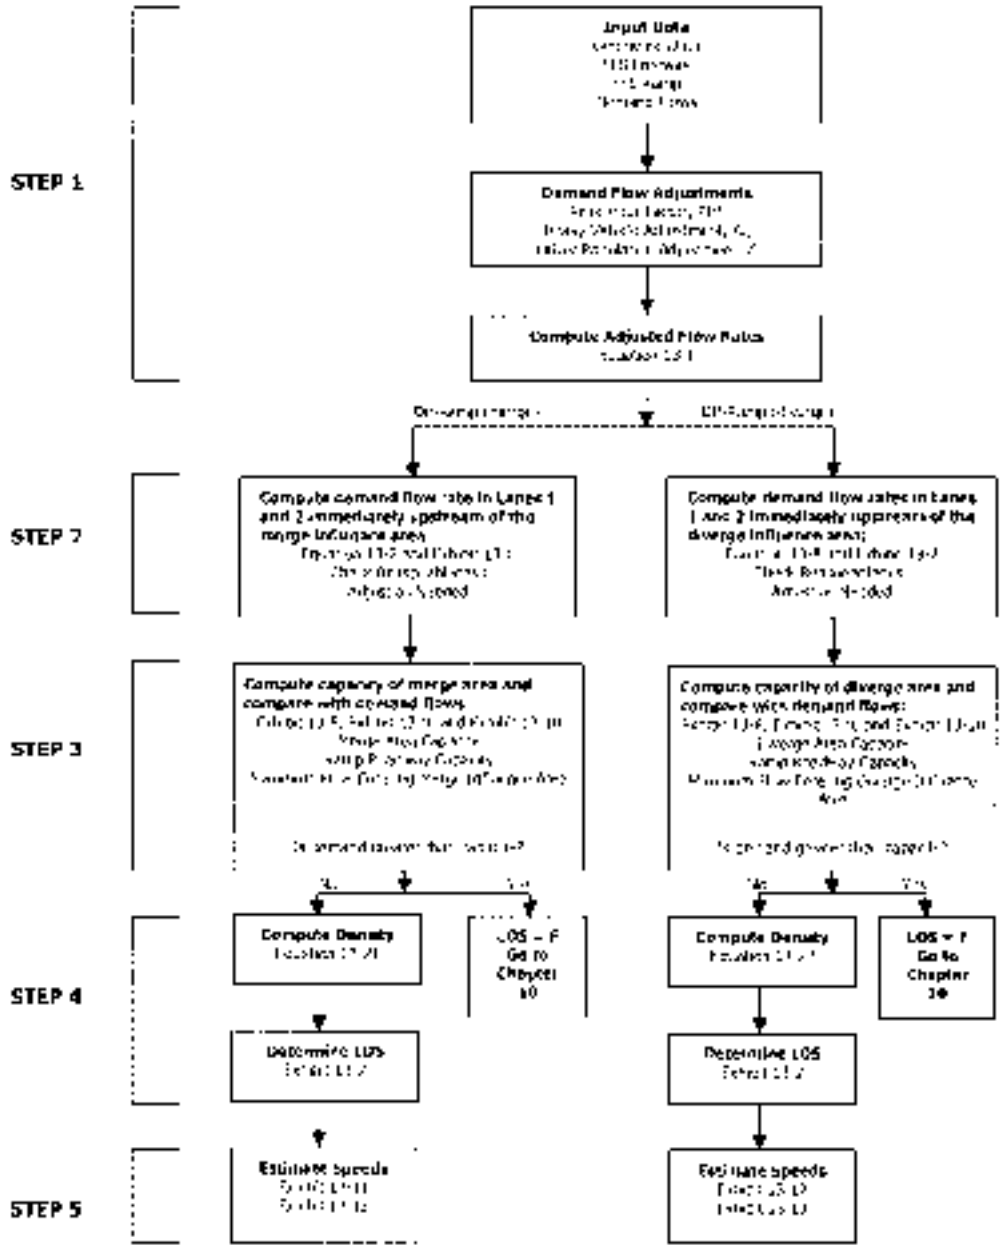
The methodology does not explicitly take into account posted speed limits or level of police enforcement. In some cases, low speed limits and strict enforcement could result in lower speeds and higher densities than those anticipated by this methodology.

OVERVIEW

Exhibit 13-4 illustrates the computational methodology applied to the analysis of ramp–freeway junctions. The analysis is generally entered with known geometric and demand factors. The primary outputs of the analysis are LOS and capacity. The methodology estimates the density and speed in the ramp influence area.

AR0073621

Exhibit 13-4
Flowchart for Analysis of Ramp–Freeway Junctions



As previously discussed, the methodology focuses on modeling the operating conditions within the ramp influence area, as defined in Exhibit 13-1. Because the ramp influence area includes only Lanes 1 and 2 of the freeway, an important part of the methodology involves predicting the number of approaching freeway vehicles that remain in these lanes immediately upstream of the ramp–freeway junction. While operations in other freeway lanes may be affected by merging and diverging maneuvers, particularly under heavy flow, the defined influence area experiences most of the operational impacts across all levels of service (except LOS F). All breakdown, queues, and operational impacts may extend well beyond the defined influence area. Exhibit 13-5 illustrates key variables involved in the methodology.

AR0073622

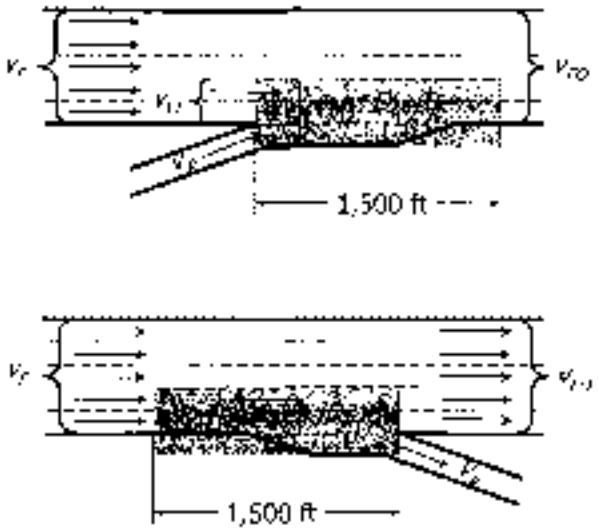


Exhibit 13-5
Key Ramp Junction Variables

The variables illustrated in Exhibit 13-5 are defined as follows:

- v_f = flow rate on freeway immediately upstream of the ramp influence area under study (pc/h),
- v_{12} = flow rate in freeway Lanes 1 and 2 immediately upstream of the ramp influence area (pc/h),
- v_{12} = flow rate on the freeway immediately downstream of the merge or diverge area (pc/h),
- v_R = flow rate on the on-ramp or off-ramp (pc/h),
- v_{12} = sum of the flow rates in Lanes 1 and 2 and the ramp flow rate (on ramps only) (pc/h),
- D_R = density in the ramp influence area (pc/mi/ln), and
- S_R = average speed in the ramp influence area (mi/h).

The computational process illustrated in Exhibit 13-4 may be broken into five primary steps:

1. Specify ramp input variables and convert ing demand volumes to demand flow rates in passenger cars per hour under equivalent base conditions;
2. Estimating the flow remaining in Lanes 1 and 2 at the freeway immediately up-stream of the merge or diverge influence area;
3. Estimating the capacity of the merge or diverge area and comparing the capacity with the converted demand flow rates,
4. For stable operations (i.e., demand is less than or equal to capacity), estimating the density within the ramp influence area and determining the expected LOS, and
5. When desired, estimating the average speed of vehicles within the ramp influence area.

Each step is discussed in detail in the sections that follow.

AR0073623

COMPUTATIONAL STEPS

The methodology was calibrated for one-lane, right-side ramp freeway junctions. Other situations are addressed in the Special Cases section.

The methodology described in this section was calibrated for one-lane, right-side ramp freeway junctions. All other cases—two-lane ramp junctions, left-side ramps, and major merge and diverge configurations—are analyzed with the modified procedures detailed in the Special Cases section.

Step 1: Specify Inputs and Convert Demand Volumes to Demand Flow Rates

All geometric and traffic variables for the ramp–freeway junction should be specified as inputs to the methodology, as discussed previously. Flow rates on the approaching freeway, on the ramp, and on any existing upstream or downstream adjacent ramps must be converted from hourly volumes (in vehicles per hour) to peak 15-min flow rates (in passenger cars per hour) under equivalent ideal conditions:

Equation 13-1

$$v_i = \frac{V_i}{PHF \times f_{HV} \times f_p}$$

where

v_i = demand flow rate for movement i (pc/h),

V_i = demand volume for movement i (veh/h),

PHF = peak hour factor,

f_{HV} = adjustment factor for heavy vehicle presence, and

f_p = adjustment factor for driver population.

If demand data or forecasts are already stated as 15-min flow rates, PHF is set at 1.00. Adjustment factors are the same as those used in Chapter 11, Basic Freeway Segments. These can also be used when the primary facility is a multilane highway or a C-D roadway at a freeway interchange.

Step 2: Estimate the Approaching Flow Rate in Lanes 1 and 2 of the Freeway Immediately Upstream of the Ramp Influence Area

Because the ramp influence area includes Lanes 1 and 2 of the freeway (for a right-hand ramp), a critical step in the analysis is estimating the total flow rate in Lanes 1 and 2 immediately upstream of the ramp influence area.

The distribution of freeway vehicles approaching a ramp influence area is affected by a number of variables:

- Total freeway flow approaching the ramp influence area v_f (pc/h),
- Total on- or off-ramp flow v_R (pc/h),
- Total length of the acceleration lane L_A or deceleration lane L_D (ft), and
- FFS of the ramp at the junction point S_{FR} (mi/h).

The lane distribution of approaching freeway vehicles may also be affected by adjacent upstream or downstream ramps. Nearby ramps can influence lane distribution as drivers execute lane changes to position themselves for ramp movements at adjacent ramps. An on-ramp, for example, located only a few

AR0073624

hundred feet upstream of a subject ramp may result in additional vehicles in Lanes 1 and 2 at the subject ramp. A downstream off-ramp near a subject ramp may contain additional vehicles in Lanes 1 and 2 destined for the downstream ramp.

Theoretically, the influence of adjacent upstream and downstream ramps does not depend on the size of the freeway. In practical terms, however, this methodology only accounts for such influences on six-lane freeways (three lanes in one direction). On four-lane freeways (two lanes in one direction), the determination of v_{12} is trivial, since only Lanes 1 and 2 exist; all approaching freeway vehicles are, by definition, in Lanes 1 and 2 regardless of the proximity of adjacent ramps. On eight-lane (four lanes in one direction) or larger freeways, the data are insufficient to determine the impact of adjacent ramps on lane distribution. In addition, two-lane ramps are never included as "adjacent" ramps under these procedures.

For six-lane freeways, the methodology includes a process for determining whether adjacent upstream and downstream ramps are close enough to influence lane distribution at a subject ramp junction. When such ramps are close enough, the following additional variables may be involved:

- Flow rate on the adjacent upstream ramp v_{r1} (pc/h),
- Distance between the subject ramp junction and the adjacent upstream ramp junction L_{up} (ft),
- Flow rate on the adjacent downstream ramp v_{r2} (pc/h), and
- Distance between the subject ramp junction and the adjacent downstream ramp junction L_{down} (ft).

The distance to adjacent ramps is measured between the points at which the left edge of the leftmost ramp lane meets the right-lane edge of the freeway.

In practical terms, the influence of adjacent ramps rarely extends more than approximately 8,000 ft. Nevertheless, whether an adjacent ramp on a six-lane freeway has influence should be determined by using the algorithms specified in this methodology.

Of all these variables, the total approaching freeway flow has the greatest impact on flow in Lanes 1 and 2. The models are structured to account for this phenomenon without distorting other relationships. Longer acceleration and deceleration lanes lessen turbulence as ramp vehicles enter or leave the freeway. This leads to lower densities and higher speeds in the ramp influence area. When the ramp has a higher FFS, vehicles can enter and leave the freeway at higher speeds, and approaching freeway vehicles tend to move left to avoid the possibility of high-speed turbulence. This produces greater passenger-car unit and smoother flow across all freeway lanes.

While the models are similarly structured, there are distinct differences between the lane distribution impacts of on ramps and off ramps. Separate models are presented for each case in the sections that follow.

AR0073625

Estimating Flow in Lanes 1 and 2 for On Ramps (Merge Areas)

The general model for on-ramps operations that flow in Lanes 1 and 2 immediately upstream of the merge influence area is simply a proportion of the approaching freeway flow, as shown in Equation 13-2:

Equation 13-2

$$v_{12} = v_i \times P_{FM}$$

where

v_{12} = flow rate in Lanes 1 and 2 (pc/h),

v_i = total flow rate on freeway immediately upstream of the on-ramp (merge) influence area (pc/h), and

P_{FM} = proportion of freeway vehicles remaining in Lanes 1 and 2 immediately upstream of the on-ramp influence area.

Exhibit 13-6 shows the algorithms used to determine P_{FM} for on-ramps or merge areas. All variables in Exhibit 13-6 are as previously defined.

Three equations are provided for six-lane freeways. Equation 13-3 is the base case for isolated ramps and for cases in which adjacent ramps are not found to influence merging operations. Equation 13-4 addresses cases with an upstream adjacent off ramp, while Equation 13-5 addresses cases with a downstream adjacent on-ramp. Adjacent on-ramps (either upstream or downstream) have not been found to have a statistically significant impact on operations and are therefore ignored. Equation 13-3 is applied in such cases.

Adjacent upstream or downstream ramps do not affect the prediction of v_{12} for two-lane (one direction) freeway segments, since all vehicles are in Lanes 1 and 2. Data have been insufficient to determine whether adjacent ramps influence lane distribution on four-lane (one direction) freeway segments, and thus no such impact is used in this methodology.

Where an upstream or downstream adjacent off ramp exists on a six-lane freeway, a determination as to whether the ramp is close enough to the subject merge area to influence the area's operation is necessary. The determination is made by finding the equilibrium separation distance (L_{EQ}). If the actual distance is larger than or equal to L_{EQ}, Equation 13-3 should be used. If the actual distance is shorter than L_{EQ}, then Equation 13-4 or Equation 13-5 should be used as appropriate.

Equation 13-4
Equation 13-5

SELECTING EQUATIONS FOR P_{FM} FOR SIX-LANE FREEWAYS

Adjacent Upstream Ramp	Subject Ramp	Adjacent Downstream Ramp	Equation(s) Used
None	On	None	Equation 13-3
None	On	On	Equation 13-5
None	On	Off	Equation 13-5 or 13-3
On	On	None	Equation 13-3
Off	On	None	Equation 13-4 or 13-3
On	On	On	Equation 13-3
On	On	Off	Equation 13-5 or 13-3
Off	On	On	Equation 13-4 or 13-3
Off	On	Off	Equation 13-5 or 13-4 or 13-3

Note: [a] 4 lanes = two lanes in each direction, 6 lanes = three lanes in each direction, 8 lanes = four lanes in each direction.
[b] Except for a diverge on a six-lane freeway that has a one-lane, right-side off-ramp, see Equation 13-3.

The equilibrium distance is obtained by finding the distance at which Equation 13-3 would yield the same value of P_{FM} as Equation 13-4 or Equation 13-5, as appropriate. This results in the following:

For adjacent upstream off-ramps, use Equation 13-6:

$$L_{EQ} = 0.216(v_1 - v_2) - 0.444\,L_A + 52.32\,S_{av} - 2,403 \qquad \text{Equation 13-6}$$

For adjacent downstream off-ramps, use Equation 13-7:

$$L_{EQ} = \frac{v_1}{0.1096 + 0.000107\,L_A} \qquad \text{Equation 13-7}$$

where all terms are as previously defined.

When both adjacent upstream and downstream off-ramps are present, the larger resulting value of P_{FM} is used.

A special case exists when both an upstream and a downstream adjacent off-ramp are present. In such cases, two different values of P_{FM} could arise: one from consideration of the upstream ramp and the other from consideration of the downstream ramp. They cannot be considered simultaneously. In such cases, the analysis resulting in the larger value of P_{FM} is used.

When an adjacent off-ramp to a merge area on a six-lane freeway is not a one-lane, right-side off-ramp, apply Equation 13-3.

In addition, the algorithms used to calculate the impact of an upstream or downstream off-ramp on a six-lane freeway are only valid for single-lane, right-side adjacent ramps. Where adjacent off-ramps consist of two-lane junctions or major diverge configurations, or where they are on the left side of the freeway, Equation 13-3 is always applied.

Estimating Flow in Lanes 1 and 2 for Off-Ramps (Diverge Areas)

When approaching an off-ramp (diverge area), all off-ramp traffic must be in freeway Lanes 1 and 2 immediately upstream of the ramp to execute the desired

AR0073627

maneuver. Thus, for off-ramps, the flow in Lanes 1 and 2 consists of all off-ramp vehicles and a proportion of freeway through vehicles, as in Equation 13-8:

Equation 13-8

$$v_{12} = v_R + (v_1 - v_R)P_{12}$$

where

v_1 = flow rate in Lanes 1 and 2 of the freeway immediately upstream of the deceleration lane (pc/h),

v_R = flow rate on the off-ramp (pc/h), and

P_{12} = proportion of diverging traffic remaining in Lanes 1 and 2 immediately upstream of the deceleration lane.

For off-ramps, the point at which flows are defined is the beginning of the deceleration lane(s), regardless of whether this point is within or outside the ramp influence area.

Exhibit 13-7 contains the equations used to estimate P_{12} at off-ramp diverge areas. As with the case for on-ramps (merge areas), the value of P_{12} for four-lane freeways is trivial, since only Lanes 1 and 2 exist.

Exhibit 13-7
Models for Predicting P_{12} at Off-Ramps or Diverge Areas

No. of Freeway Lanes[a]	Model(s) for Determining P_{12}
4	$P_{12} = 1.000$
6	Equation 13-9: $P_{12} = 0.760 - 0.000005v_1 - 0.000161v_R$
	Equation 13-10: $P_{12} = 0.717 - 0.000030v_1 + 0.001(v_R / (1 + v_{R,up}))$
	Equation 13-11: $P_{12} = 2.616 - 0.000021v_1 + 0.124(v_R / (1 + v_{R,up}))$
8	$P_{12} = 0.136$

SELECTING EQUATIONS FOR P_{12} FOR SIX-LANE FREEWAYS

Adjacent Upstream Ramp	Subject Ramp	Adjacent Downstream Ramp	Equation(s) Used
None	Off	None	Equation 13-9
None	Off	On	Equation 13-9
None	Off	Off	Equation 13-11 or 13-9
On	Off	None	Equation 13-10 or 13-9
Off	Off	None	Equation 13-9
On	Off	On	Equation 13-10 or 13-9
On	Off	Off	Equation 13-11, 13-10, or 13-9
Off	Off	On	Equation 13-9
Off	Off	Off	Equation 13-11 or 13-9

Note: Adjacent = two successive ramps in the same direction of travel along the freeway; Subject = the ramp under consideration.

a. If an adjacent ramp on a six-lane freeway is not a one-lane, right-side off-ramp, use Equation 13-9.

For six-lane freeways, three equations are presented. Equation 13-9 is the base case for isolated ramps or for cases in which the impact of adjacent ramps can be ignored. Equation 13-10 addresses cases in which there is an adjacent upstream on-ramp, while equation 13-11 addresses cases in which there is an adjacent downstream off-ramp. Adjacent upstream off-ramps and downstream on-ramps have not been found to have a statistically significant impact on diverge operations and may be ignored. All variables in Exhibit 13-7 are as previously defined.

AR0073628

Insufficient information is available to establish an impact of adjacent ramps on eight-lane freeways (four lanes in each direction). This methodology does not include such an impact.

Where an adjacent upstream on-ramp or downstream off-ramp on a six-lane freeway exists, a determination as to whether the ramp is close enough to the subject off-ramp to affect its operation is necessary. As was the case for on-ramps, this is done by finding the equilibrium distance L_{EQ}. This distance is determined when Equation 13-9 yields the same value of P_{FD} as Equation 13-10 (for adjacent upstream on-ramps) in Equation 13-11 (adjacent downstream off-ramps). When the actual distance between ramps is greater than or equal to L_{EQ}, Equation 13-9 is used. When the actual distance between ramps is less than L_{EQ}, Equation 13-10 or Equation 13-11 is used as appropriate.

For adjacent upstream on-ramps, use Equation 13-12 to find the equilibrium distance:

$$L_{EQ} = \frac{v_R}{0.071 - 0.000023v_1 - 0.000076v_R}$$

Equation 13-12

For adjacent downstream off-ramps, use Equation 13-13:

$$L_{EQ} = \frac{v_D}{1.15 - 0.000032v_1 - 0.000369v_R}$$

Equation 13-13

where all terms are as previously defined.

A special case exists when both an adjacent upstream on-ramp and an adjacent downstream off-ramp are present. In such cases, two solutions for P_{FD} may arise, depending on which adjacent ramp is considered (both ramps cannot be considered simultaneously). In such cases, the larger value of P_{FD} is used.

When both an adjacent upstream on-ramp and an adjacent downstream off-ramp are present, the larger resulting value of P_{FD} is used.

As was the case for merge areas, the algorithms used to include the impact of an upstream or downstream ramp on a six-lane freeway are only valid for single-lane, right-side adjacent ramps. Where adjacent ramps consist of two-lane junctions or major diverge configurations, or where they are on the left side of the freeway, Equation 13-9 is always applied.

When an adjacent ramp is a diverge area on a six-lane freeway or has a two-lane, one-side ramp, apply Equation 13-9.

Checking the Reasonableness of the Lane Distribution Prediction

The algorithms of Exhibit 13-6 and Exhibit 13-7 were developed through regression analysis of a large database. Unfortunately, regression based models may yield unreasonable or unexpected results when applied outside the actual limits of the calibration database, and they may have inconsistencies at their boundaries.

Reasonableness checks on the value of v_{12}

Therefore, it is necessary to apply some limits to predicted values of flow in Lanes 1 and 2 (v_{12}). The following limitations apply to all such predictions:

1. The average flow per lane in the outer lanes of the freeway (lanes other than 1 and 2) should not be higher than 2,700 pc/h/ln.
2. The average flow per lane in outer lanes should not be higher than 1.5 times the average flow in Lanes 1 and 2.

AR0073629

These limits guard against cases in which the predicted value of v_1 implies an unreasonably high flow rate in outer lanes of the freeway. When either of these limits is violated, an adjusted value of v_1 must be computed and used in the remainder of the methodology.

Application to Six-Lane Freeways

On a six-lane freeway (three lanes in one direction), there is only one outer lane to consider. The flow rate in this outer lane (Lane 3) is given by Equation 13-14:

Equation 13-14

$$v_3 = v_1 - v_2$$

where

v_3 = flow rate in Lane 3 of the freeway (pc/h/ln),

v_2 = flow rate on freeway immediately upstream of the ramp influence area (pc/h), and

v_1 = flow rate in Lanes 1 and 2 immediately upstream of the same influence area (pc/h).

Then, if v_3 is greater than 2,700 pc/h, use Equation 13-15.

Equation 13-15

$$v_{12a} = v_1 - 2{,}700$$

If v_3 is greater than $1.5 \times (v_1/2)$, use Equation 13-16.

Equation 13-16

$$v_{12a} = \left(\frac{v_1}{1.75}\right)$$

where v_{12a} equals the adjusted flow rate in Lanes 1 and 2 immediately upstream of the ramp influence area (pc/h) and all other variables are as previously defined.

In cases where both limitations on outer lane flow rate are violated, the result yielding the highest value of v_{12a} is used. The adjusted value replaces the original value of v_1, and the analysis continues.

Application to Eight-Lane Freeways

On eight-lane freeways, there are two outer lanes (Lanes 3 and 4). Thus, the limiting values cited previously apply to the average flow rate per lane in these lanes. The average flow in these lanes is computed from Equation 13-17:

Equation 13-17

$$v_{34} = \frac{v_3 + v_4}{2}$$

where v_{34} equals the flow rate in outer lanes (pc/h/ln) and all other variables are as previously defined.

Then, if v_{34} is greater than 2,700, use Equation 13-18:

Equation 13-18

$$v_{12a} = v_1 - 5{,}400$$

If v_{12a} is greater than $1.5 \times (v_1/2)$, use Equation 13-19.

Equation 13-19

$$v_{12a} = \left(\frac{v_1}{2.50}\right)$$

AR0073630

where all terms are as previously defined.

In cases where both limitations on ramp flow rate are violated, the result yielding the highest value of v_{12} is used. The adjusted value replaces the original value of v_{12} and the analysis continues.

Summary of Step 2

At this point, an appropriate value of v_{12} has been computed and adjusted as necessary.

Step 3: Estimate the Capacity of the Ramp–Freeway Junction and Compare with Demand Flow Rates

There are three major checkpoints for the capacity of a ramp–freeway junction:

Locations for checking the capacity of a ramp–freeway junction

1. The capacity of the freeway immediately downstream of an on-ramp or immediately upstream of an off-ramp.
2. The capacity of the ramp roadway, and
3. The maximum flow rate entering the ramp influence area.

Freeway capacity immediately downstream of an on-ramp or upstream of an off-ramp is usually the controlling capacity value.

In most cases, the freeway capacity is the controlling factor. Studies (*1*) have shown that the turbulence in the vicinity of a ramp–freeway junction does not diminish the capacity of the freeway.

Failure of a merge maneuver is usually caused by a capacity deficiency at the ramp–street terminal or on the off-ramp roadway.

The capacity of the ramp roadway is rarely a factor at on-ramps, but it can play a major role at off-ramp (diverge) junctions. Failure of a diverge junction is most often caused by a capacity deficiency on the off-ramp roadway or at its ramp–street terminal.

While this methodology establishes a maximum desirable rate of flow entering the ramp influence area, exceeding this value does not cause a failure. Instead, it means that operations may be less desirable than indicated by the methodology. At off-ramps, the total flow rate entering the ramp influence area is merely the estimated value of v_{12}. At on-ramps, however, the on-ramp flow also enters the ramp influence area. Therefore, the total flow entering the ramp influence area at an on-ramp is given by Equation 13-20:

$$v_{r(o)} = v_{12} + v_o \quad \text{Equation 13-20}$$

where $v_{r(o)}$ is the total flow rate entering the ramp influence area at an on-ramp (pc/h) and all other variables are as previously defined.

Exhibit 13-8 shows capacity values for ramp–freeway junctions. Exhibit 13-9 shows similar values for high-speed ramps on multilane highways and C-D roadways within freeway interchanges. Exhibit 13-10 shows the capacity of ramp roadways.

FFS (mi/h)	Capacity of Upstream/Downstream Freeway Segment[a] No. of Lanes in One Direction 2	3	4	>4	Max. Desirable Flow Rate (v_{MAX}) Entering Merge Influence Area[b]	Max. Desirable Flow Rate (v_{MAX}) Entering Diverge Influence Area[b]
>70	4,900	7,200	9,800	2,400/ln	4,600	4,400
65	4,700	7,050	9,400	2,350/ln	4,600	4,400
60	4,600	6,900	9,200	2,300/ln	4,600	4,400
55	4,500	6,750	9,000	2,250/ln	4,600	4,400

Notes: [a] Demand in excess of these capacities results in LOS F.
[b] Demand in excess of these values but not in excess of capacity results in LOS F; operations may be worse than predicted by this methodology.

Exhibit 13-9
Capacity of High-Speed Ramp Junctions on Multilane Highways and C-D Roadways (pc/h)

FFS (mi/h)	Capacity of Upstream/Downstream Highway or C-D Segment[a] No. of Lanes in One Direction 2	3	>3	Max. Desirable Flow Rate (v_{MAX}) Entering Merge Influence Area[b]	Max. Desirable Flow Rate (v_{MAX}) Entering Diverge Influence Area[b]
>60	4,400	6,600	2,200/ln	4,600	4,400
55	4,200	6,300	2,100/ln	4,600	4,400
50	4,000	6,000	2,000/ln	4,600	4,400
45	3,800	5,700	1,900/ln	4,600	4,400

Notes: [a] Demand in excess of these capacities results in LOS F.
[b] Demand in excess of these values but not in excess of capacity results in LOS F; operations may be worse than predicted by this methodology.

Exhibit 13-10
Capacity of Ramp Roadways (pc/h)

Ramp FFS S_{FR} (mi/h)	Capacity of Ramp Roadway Single-Lane Ramps	Two-Lane Ramps
>50	2,200	4,400
>40–50	2,100	4,200
>30–40	2,000	4,000
≥20–30	1,900	3,800
<20	1,800	3,600

Note: Capacity of a ramp roadway does not ensure an equal capacity at a freeway or other high-speed junction. Junction capacity must be checked against criteria in Exhibit 13-8 and Exhibit 13-9.

Ramp–Freeway Junction Capacity Checkpoint

As noted previously, it is generally the capacity of the upstream or downstream freeway segment that limits flow through a merge or diverge area, assuming that the number of freeway lanes entering and leaving the ramp junction is the same. In such cases, the critical checkpoint for freeway capacity is

- Immediately downstream of an on-ramp influence area (v_{12}), or
- Immediately upstream of an off-ramp influence area (v_1).

These are logical checkpoints, since each represents the point at which maximum freeway flow exists.

When a ramp junction or major merge/diverge area involves lane additions or lane drops at the junction, freeway capacity must be checked both immediately upstream and downstream of the ramp influence area.

Failure of any ramp–freeway junction capacity check results in LOS F

Failure of any ramp–freeway junction capacity check (i.e., demand exceeds capacity, or v/c is greater than 1.0) results in LOS F.

Ramp Roadway Capacity Checkpoint

The capacity of the ramp roadway should always be checked against the demand flow rate on the ramp. For one-ramp on merge junctions, this is rarely a problem. Theoretically, cases could exist in which demand exceeds capacity. A

AR0073632

failure due to insufficient on-ramp capacity does not, in itself, create problems on the freeway. Rather, it would result in queuing at the street-side terminal of the ramp (or in the case of a freeway-to-freeway ramp, on the entering freeway).

At off-ramps or diverge areas, the most frequent cause of failure is insufficient capacity on the off-ramp—due to either the ramp roadway or a failure at the ramp–street terminal. This methodology checks only for the off-ramp roadway capacity. The capacity of the ramp–street junction must be evaluated by using appropriate methodologies for unsignalized intersections (Chapter 19, 20, or 21) or signalized interchange ramp terminals (Chapter 22).

If the off-ramp demand flow rate v_R exceeds the capacity of the off-ramp, LOS F prevails. If appropriate analysis results in a finding that the ramp–street terminal is operating at a v/c ratio greater than 1.00 on the ramp approach leg, a queuing analysis should be conducted to evaluate (a) the extent of the queue that is likely to exist on the ramp roadway and (b) whether the queue is close enough to the ramp–freeway junction to affect its operation negatively.

Maximum Desirable Flow Entering the Ramp Influence Area

When a checkpoint for v_R (off-ramps) or v_{FO} (on-ramps) is conducted, failure does not result in assignment of LOS F, unless another failure occurs on a ramp roadway or freeway segment. Failing this checkpoint generally means that there will be more turbulence in the ramp junction influence area than predicted by this methodology. Thus, predicted densities are most likely lower than those that will exist, and predicted speeds are most likely higher than those that will actually occur.

Failure of the check on flow entering the ramp influence area (v_{12}, Veh) does not automatically result in LOS F, but does indicate the need for additional analysis of the results.

Step 4: Estimate Density in the Ramp Influence Area and Determine the Prevailing LOS

Once the flow rate in Lanes 1 and 2 immediately upstream of the ramp influence area is determined, the expected density in the ramp influence area can be estimated.

Density in On-Ramp (Merge) Influence Areas

The density in on-ramp influence areas is estimated with Equation 13-21.

$$D_R = 5.475 + 0.00734 v_R + 0.0078 v_{12} - 0.00627 L_A \quad \text{Equation 13-21}$$

where D_R is the density in the ramp influence area (pc/mi/ln) and all other variables are as previously defined.

The equation is logical. As more on-ramp vehicles and freeway vehicles in Lanes 1 and 2 enter the ramp influence area, its density is expected to increase. As the length of the acceleration lane increases, there is more physical space in the ramp influence area, and operating speeds of merging vehicles are expected to increase—both tending to reduce densities.

Density in Off-Ramp (Diverge) Influence Areas

The density in off-ramp influence areas is estimated with Equation 13-22:

$$D_R = 4.252 + 0.0086 v_{12} - 0.009 L_A \quad \text{Equation 13-22}$$

AR0073633

where all variables are as previously defined.

This equation also follows logical trends. There is no separate term for v_R because it is included in v_F for off-ramps. As the number of vehicles entering the ramp influence area increases, density increases. As the length of the deceleration lane increases, the additional space provided and the resulting higher speeds of merging vehicles both act to reduce density.

Determining LOS

LOS in ramp influence areas is directly related to the estimated density within the area, as given by Equation 13-21 or Equation 13-22. Exhibit 13-9, shown previously, contains the criteria for this determination. Note again that density definitions of LOS apply only to stable flow (i.e., LOS A–E). LOS F exists only when the capacity of the ramp junction is insufficient to accommodate the existing or projected demand flow rate.

If it is determined that a merge or diverge segment is operating (or expected to operate at) LOS F, the analyst should go to Chapter 10, Freeway Facilities, and conduct a facility analysis that will estimate the spatial and time impacts of queuing resulting from the breakdown.

Step 5: Estimate Speeds in the Vicinity of Ramp–Freeway Junctions

While an estimation of average vehicle speeds in and adjacent to ramp influence areas is not necessary, it is often a useful additional performance measure. Two types of speeds may be estimated:

- Average speed of vehicles within the ramp influence area (mi/h), and
- Average speed of vehicles across all lanes (including outer lanes) within the 1,500-ft length of the ramp influence area (mi/h).

Both types of speeds are needed when a freeway facility analysis is conducted (Chapter 10), while the first type of speed provides a useful companion measure to density within the ramp influence area in all cases.

Exhibit 13-11 and Exhibit 13-12 provide equations for estimating the average speed of vehicles (a) within the ramp influence area and (b) in outer lanes of the freeway adjacent to the 1,500-ft ramp influence area. For four-lane freeways (two lanes in each direction), there are no "outer lanes." For six-lane freeways (three lanes in each direction), there is one outer lane (Lane 3). For eight-lane freeways (four lanes in each direction), there are two outer lanes (Lanes 3 and 4). Exhibit 13-13 provides equations to determine the average speed of all vehicles (ramp plus all freeway vehicles) within the 1,500-ft length of the ramp influence area.

Average speed for off-ramp (diverge) junctions (mi/h)	$S = \frac{v_{12} + v_{34}N_{34}}{v_{12} + v_{34}N_{34}\left(\frac{S_{12}}{S_{34}}\right)}$

Exhibit 13-13
Estimating Average Speed of All Vehicles at Ramp–Freeway Junctions

While many (but not all) of the variables in Exhibit 13-13, Exhibit 13-12, and Exhibit 13-14 have been defined previously, all are defined here for convenience:

S_R = average speed of vehicles within the ramp influence area (mi/h); for merge areas, this includes all ramp and freeway vehicles in Lanes 1 and 2; for diverge areas, this includes all vehicles in Lanes 1 and 2,

S_{12} = average speed of vehicles in outer lanes of the freeway, adjacent to the 1,500-ft ramp influence area (mi/h);

S = average speed of all vehicles in all lanes within the 1,500-ft length covered by the ramp influence area (mi/h),

FFS = free-flow speed of the freeway (mi/h),

S_R = free-flow speed of the ramp (mi/h);

L_A = length of acceleration lane (ft),

L_D = length of deceleration lane (ft);

v_R = demand flow rate on ramp (pc/h);

v_{12} = demand flow rate in Lanes 1 and 2 of the freeway immediately upstream of the ramp influence area (pc/h);

v_{FO} = total demand flow rate entering the ramp influence area, including v_R and v_{12} (pc/h);

v_{12} = average demand flow per lane in outer lanes adjacent to the ramp influence area (not including flow in Lanes 1 and 2) (pc/h/ln);

v_F = demand flow rate on freeway immediately upstream of the ramp influence area (pc/h),

N_O = number of outer lanes on the freeway (3 for a six-lane freeway; 2 for an eight-lane freeway);

MI_R = speed index for on-ramps (merge areas); this is simply an intermediate

AR0073635

computation that simplifies the equations, and

(1) = speed index for off-ramps (diverge areas), this is simply an intermediate computation that simplifies the equations.

Exhibit 13-11, Exhibit 13-12, and Exhibit 13-13 only apply to Basic Ramp conditions. Consult Chapter 10 for analysis of oversaturated conditions.

The equations in Exhibit 13-11, Exhibit 13-12, and Exhibit 13-13 apply only to cases in which operation is stable (LOS A–E). Analysis of operational details for cases in which LOS F is present relies on deterministic queuing approaches, as presented in Chapter 10, Freeway Facilities.

Flow rates in outer lanes can be higher than the values cited for basic freeway segments. The basic freeway segment values represent averages across all freeway lanes, not flow rates in a single lane or a subset of lanes. The methodology herein allows flows in outer lanes to be as high as 2,700 pc/h/ln. The equations for average speed in outer lanes were based on a database that included average outer lane flows as high as 2,088 pc/h/ln while still maintaining stable flow. Values over 2,700 pc/h/ln, however, are unusual and cannot be expected in the majority of situations.

In addition, the equations of Exhibit 13-11 do not allow a predicted speed over the FFS for merge areas. For diverge areas at low flow rates, however, the average speed in outer lanes may marginally exceed the FFS. As with average lane flow rates, the FFS is stated as an average across all lanes, and speeds in individual lanes can exceed this value. Despite this, the average speed of all vehicles *S* should be limited to a maximum value equal to the FFS.

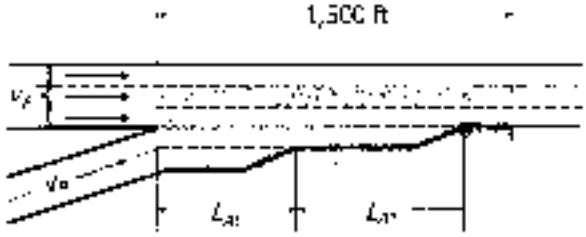
SPECIAL CASES

As noted previously, the computational procedure for ramp-freeway junctions was calibrated for single-lane, right-side ramps. Many other merge and diverge configurations may be encountered, however. In these cases, the general methodology is modified to account for special situations. These modifications are discussed in the sections that follow.

Two-Lane On-Ramps

Exhibit 13-14 illustrates the geometry of a typical two-lane ramp-freeway junction. It is characterized by two separate acceleration lanes, each successively forcing merging maneuvers to the left.

Exhibit 13-14
Typical Geometry of a Two-Lane Ramp-Freeway Junction



Two-lane on-ramps entail two modifications to the basic methodology: the flow remaining in Lanes 1 and 2 immediately upstream of the on-ramp influence area is generally somewhat higher than it is for one-lane on-ramps in similar situations, and densities in the merge influence area are lower than those for similar one-lane on-ramp situations. The lower density is primarily due to the

AR0073636

existence of two acceleration lanes and the generally longer distance over which these lanes extend. Thus, two-lane on-ramps handle higher ramp flows more smoothly and at a better LOS than if the same flows were carried on a one-lane ramp–freeway junction.

Two-lane on-ramp–freeway junctions, however, do not enhance the capacity of the junction. The downstream freeway capacity still controls the total output capacity of the merge area, and the maximum desirable number of vehicles entering the ramp influence area is not changed.

There are three computational modifications to the general methodology for two-lane on-ramps.

First, while v_{12} is still estimated as $v_R \times P_{FM}$, the values of P_{FM} are modified as follows:

- For four-lane freeways: P_{FM} = 1.000;
- For six-lane freeways: P_{FM} = 0.555; and
- For eight-lane freeways: P_{FM} = 0.289.

Second, in all equations using the length of the acceleration lane L_A, this value is replaced by the effective length of both acceleration lanes L_{EA} from Equation 13-23:

$$L_{EA} = 2L_A + L_G \quad \text{Equation 13-23}$$

A two-lane ramp is always considered to be isolated (i.e., no adjacent ramp conditions affect the computation).

Component lengths are as illustrated in Exhibit 13-14.

Two-Lane Off-Ramps

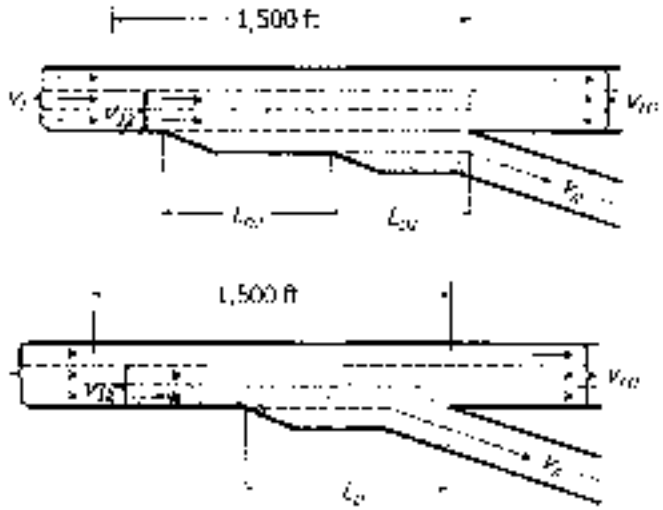
Two common types of diverge geometries are in use with two-lane off-ramps, as shown in Exhibit 13-15. In the first, two successive deceleration lanes are introduced. In the second, a single deceleration lane is used. The left-hand ramp lane splits from Lane 1 of the freeway at the gore area, without a deceleration lane.

As is the case for two-lane on-ramps, there are three computational step modifications. While v_{12} is still computed as $v_{12} = (v_R + v_F) \times P_{FD}$, the values of P_{FD} are modified as follows:

- For four-lane freeways: P_{FD} = 1.000;
- For six-lane freeways: P_{FD} = 0.450; and
- For eight-lane freeways: P_{FD} = 0.260.

AR0073637

Exhibit 13-15
Common Geometries for Two-Lane Off-Ramp–Freeway Junctions



Where a single deceleration lane is used, there is no modification to the length of the deceleration lane L_d; where two deceleration lanes exist, the length is replaced by the effective length L_{ea} in all equations, obtained from Equation 13-24:

Equation 13-24

$$L_{ea} = 2L_d + L_{d2}$$

A two-lane ramp is always considered to be isolated (i.e., no adjacent ramp conditions affect the computation).

Component lengths are as illustrated in Exhibit 13-15.

The capacity of a two-lane off-ramp is essentially equal to that of a single two-lane off-ramp.

The capacity of a two-lane off-ramp freeway junction is essentially equal to that of a similar one-lane off-ramp; that is, the total flow capacity through the diverge is unchanged. It is limited by the upstream freeway, the downstream freeway, or the off-ramp capacity. While the capacity is not affected by the presence of two-lane junctions, the lane distribution of vehicles is more flexible than in a similar one-lane case. The two-lane junctions may also be able to accommodate a higher off-ramp flow than can a single-lane off-ramp.

Left-Hand On- and Off-Ramps

While they are not commonly accommodated, left-hand ramps (freeway continues to exist on same freeways, and they occur frequently on C-D roadways. The left-hand ramp influence area covers the same 1,500-ft length as that of right-hand ramps—upstream of off-ramps, downstream of on-ramps.

For right-hand ramps, the ramp influence area involves Lanes 1 and 2 of the freeway. For left-hand ramps, the ramp influence area involves the two leftmost lanes of the freeway. For four-lane freeways (two lanes in each direction), this does not involve any changes, since only Lanes 1 and 2 exist. For six-lane freeways (three lanes in each direction), the flow in Lanes 2 and 3 (v_{12}) is involved. For eight-lane freeways (four lanes in each direction), the flow in Lanes 3 and 4 (v_{34}) is involved.

AR0073638

While there is no direct methodology for the analysis of left-hand ramps, some rational modifications can be applied to the right-hand ramp methodology to produce reasonable results (3).

It is suggested that analysts compute v_{12} as if the ramp were on the right. An estimate of the appropriate flow rate in the two leftmost lanes is then obtained by multiplying the result by the adjustment factors shown in Exhibit 13-16.

Freeway Size	Adjustment Factor for Left-Hand Ramps	
	On-Ramps	Off-Ramps
Four-lane	1.00	1.00
Six-lane	1.12	1.05
Eight-lane	1.20	1.10

Exhibit 13-16
Adjustment Factors for Left-Hand Ramp–Freeway Junctions

The remaining computations for density and speed determination by using the values of v_{12} (six-lane freeways) or v_{34} (eight-lane freeways) as appropriate. All capacity values remain unchanged.

Ramp–Freeway Junctions on 10-Lane Freeways (Five Lanes in Each Direction)

Freeway segments with five continuous lanes in a single direction are becoming more common in North America. A procedure is therefore needed to analyze a single-lane, right-hand on- or off-ramp on such a segment.

The approach taken is relatively simple: estimate the flow in Lane 5 of such a segment and deduct it from the approaching freeway flow v_f. With the Lane 5 flow deducted, the segment can now be treated as if it were an eight-lane freeway (4). Exhibit 13-17 shows the recommended values for flow rate in Lane 5 of these segments.

On-Ramps		Off-Ramps	
Approaching Freeway Flow v_f (pc/h)	Approaching Lane 5 Flow v_5 (pc/h)	Approaching Freeway Flow v_f (pc/h)	Approaching Lane 5 Flow v_5 (pc/h)
≥8,500	2,500	≥7,000	0.200 v_f
7,500–8,499	0.265 v_f	5,500–6,999	0.150 v_f
6,500–7,499	0.270 v_f	4,000–5,499	0.100 v_f
5,500–6,499	0.240 v_f	<4,000	0
<5,500	0.220 v_f		

Exhibit 13-17
Expected Flow in Lane 5 of a 10-Lane Freeway Immediately Upstream of a Ramp–Freeway Junction

Once the expected flow in Lane 5 is determined, the effective total freeway flow rate in the remaining four lanes is computed from Equation 13-25.

$$v_{f(4)} = v_f - v_5 \quad \text{Equation 13-25}$$

where

$v_{f(4)}$ = effective approaching freeway flow in four lanes (pc/h),

v_f = total approaching freeway flow in five lanes (pc/h), and

v_5 = estimated approaching freeway flow in Lane 5 (pc/h).

The remainder of the analysis uses the adjusted approaching freeway flow rate and treats the geometry as if it were a single-lane, right-hand ramp junction on an eight-lane freeway (four lanes in each direction).

AR0073639

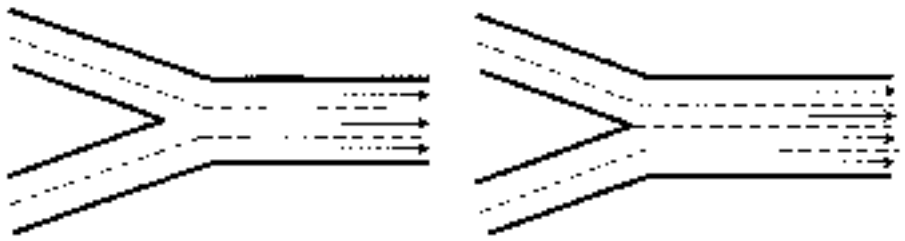
There is no calibrated procedure for adapting the methodology of this chapter to freeways with more than five lanes in one direction. The approach of Equation 13-25 is, however, conceptually adaptable to such situations. A local calibration of the amount of traffic using Lanes 5+ would be needed. The remaining flow could then be modeled as if it were taking place on a four-lane (one direction) segment.

Major Merge Areas

A major merge area is one in which two primary roadways, each having multiple lanes, merge to form a single freeway segment. Such junctions occur when two freeways join to form a single freeway or when a major multilane high-speed ramp joins with a freeway. Major merges are different from one- and two-lane on ramps in that each of the merging roadways is generally at or near freeway design standards and no clear ramp or acceleration lane is involved in the merge.

Such merge areas come in a variety of geometries, all of which fall into one of two categories. In one geometry, the number of lanes leaving the merge area is one less than the total number of lanes entering it. In the other, the number of lanes leaving the merge area is the same as that entering it. These geometries are illustrated in Exhibit 13-18.

Exhibit 13-18
Major Merge Areas Illustrated



(a) Major Merge with One Lane Dropped (b) Major Merge with No Lane Dropped

There are no effective models of performance for a major merge area. Therefore, analysis is limited to checking capacities on the approaching legs and the downstream freeway segment. A merge failure would be indicated by a v/c ratio in excess of 1.00. LOS cannot be determined for major merge areas. Problems in major merge areas usually result from insufficient capacity of the downstream freeway segment.

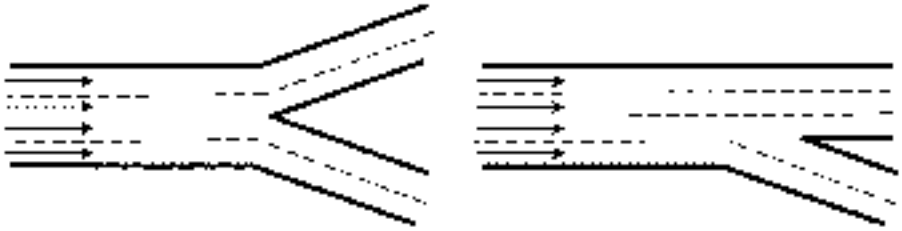
LOS cannot be determined for major merge areas.

Major Diverge Areas

The two common geometries for major diverge areas are illustrated in Exhibit 13-19. In the first case, the number of lanes leaving the diverge area is the same as the number entering it. In the second, the number of lanes leaving the diverge area is one more than the number entering it.

The principal analysis of a major diverge area involves checking the capacity of entering and departing roadways, all of which are generally built to mainline standards. A failure results when any of the demand flow rates exceeds the capacity of the segment.

AR0073640



(a) Major Diverge Area with No Lane Addition (b) Major Diverge Area with Lane Addition

Exhibit 13-19
Major Diverge Areas Illustrated

For major diverge areas, a model exists for computing the average density across all approaching freeway lanes within 1,500 ft of the diverge, as given in Equation 13-26.

$$D_{MD} = 0.0175\left(\frac{v_f}{N}\right) \quad \text{Equation 13-26}$$

where

D_{MD} = density in the major diverge influence area (which includes all approaching freeway lanes) (pc/mi/ln),

v_f = demand flow rate immediately upstream of the major diverge influence area (pc/h), and

N = number of lanes approaching the major diverge.

The result can be compared with the criteria of Exhibit 13-2 to determine a LOS for the major diverge influence area. Note that the density and LOS estimates are only valid for stable cases (i.e., not in cases in which LOS F exists because of a capacity deficiency on the approaching or departing legs of the diverge).

Effect of Ramp Control at On-Ramps

For the purposes of this methodology, procedures are not modified in any way to account for the local effect of ramp control. Except for the limitation that the ramp meter may have on the ramp demand flow rate. Research (5) has found that the breakdown of a merge area may be a probabilistic event based on the platoon characteristics of the arriving ramp vehicles. Ramp meters can dictate uniform gaps between entering ramp vehicles and may reduce the probability of a breakdown on the associated freeway mainline.

OVERLAPPING RAMP INFLUENCE AREAS

Whenever a series of ramps on a freeway is analyzed, the 1,500-ft ramp influence areas could overlap. In such cases, the operation in the overlapping region is determined by the ramp influence area having the highest density.

AR0073641

3. APPLICATIONS

The methodology of this chapter is most often used to estimate the capacity and LOS of ramp–freeway junctions. The steps are most easily applied in the operational analysis mode (i.e., all traffic and roadway conditions are specified), and the capacity (and v/c ratio) and expected LOS are found. Other types of analysis, however, are possible.

DEFAULT VALUES

A comprehensive presentation of potential default values for uninterrupted-flow facilities is provided elsewhere (6). Chapter 10, Freeway Facilities, provides a summary of the default values for freeways. These defaults cover the key characteristics of peak hour factor (PHF) and percent heavy vehicles (%HV) on freeways. Recommendations are based on geographical region, population, and time of day. All general freeway default values may be applied to the analysis of ramp–freeway junctions in the absence of field data or projections of conditions.

Because of the number of variables involved in the analysis of ramps, which have been discussed previously, it is difficult to base an analysis on too many default values. Clearly, all demand flow rates must be specified, even if they are projections.

Basic geometric characteristics cover a variety of conditions; default values should be avoided if possible.

Similarly, geometric characteristics of ramps cover a wide variety of conditions. If absolutely necessary, the following additional default values may be applied to a ramp junction analysis:

- Length of acceleration lane L_A = 800 ft.
- Length of deceleration lane L_D = 400 ft.
- FFS of ramp S_{FR} = Straight and
- Driver population factor f_P = 1.00.

Obviously, as the number of default values used in any analysis increases, the accuracy of the result becomes more approximate, and the result may be significantly different from the actual outcome (depending on local conditions). If locally calibrated default values are available, they may be substituted for the values above.

ESTABLISH ANALYSIS BOUNDARIES

No ramp–freeway junction is completely isolated. However, for the purposes of this methodology, many may operate as if they were. In the analyses of ramp–freeway junctions, it is important to establish the segment of freeway over which ramp–junctions are to be analyzed. Once this is done, each ramp may be analyzed in conjunction with the possible impacts of upstream and downstream adjacent ramps according to the methodology.

Analysis boundaries may also include different demand scenarios related to the time of the day or to different development scenarios that produce different demand flow rates.

AR0073642

Any application of the methodology presented in this chapter can be made easier by carefully defining the spatial and time boundaries of the analysis.

TYPES OF ANALYSIS

The methodology of this chapter can be used in three types of analysis: operational analysis, design analysis, and planning and preliminary design analysis.

Operational Analysis

Operational analysis determines density, LOS, and speed within the merge influence area for a specified set of conditions.

The methodology is most easily applied in the operational analysis mode. In operational analysis, all traffic and geometric characteristics of the analysis segment must be specified, including:

- Analysis hour demand volumes for the subject ramp, adjacent ramps, and freeway (veh/h);
- Heavy vehicle percentages for all component demand volumes (ramps, adjacent ramps, freeway);
- PHF for all component demand volumes (ramp, adjacent ramps, freeway);
- Freeway terrain (level, rolling, mountainous, specific grade);
- FFS of the freeway and ramp (mi/h);
- Ramp geometrics: number of lanes, terrain, length of acceleration lane(s) or deceleration lane(s), and
- Distance to upstream and downstream adjacent ramps (ft).

The outputs of an operational analysis will be estimates of density, LOS, and speed for the ramp influence area. The capacity of the ramp–freeway junction will also be established.

The steps of the methodology, described in the Methodology section, are to be followed directly without modification.

Design Analysis

Design analysis is used to determine the geometric characteristics of the ramp that are needed to deliver a target LOS.

In design analysis, a target LOS is set and all relevant demand volumes are specified. The analysis seeks to determine the geometric characteristics of the ramp that are needed to deliver the target LOS. These characteristics include:

- FFS of the ramp S_R (mi/h),
- Length of acceleration L_A or deceleration lane L_D (ft), and
- Number of lanes on the ramp.

In some cases, variables such as the type of junction (e.g., major merge, two-lane) may also be under consideration.

There is no convenient way to compute directly the optimal value of any one variable without specifying all of the others. Even then, the computational methodology does not easily create the desired result.

Therefore, most design analysis becomes a trial and error application of the operational analysis procedure. Individual characteristics can be incrementally

AR0073643

changed, as can groups of characteristics, to find scenarios that produce the desired LOS.

In many cases, some of the variables may be fixed by site-specific conditions. These can be set at their limiting values before attempting to optimize the others.

It is possible to program a spreadsheet to complete such an analysis, providing scenario results by simply changing some of the input variables under consideration. HCM-implementing software can also be used to simplify the computational process.

Planning and Preliminary Engineering Analysis

Planning and preliminary engineering analysis also seeks to determine the geometric characteristics of the ramp that are needed to achieve a target LOS, but it relies on more general input data.

The desired outputs of planning and preliminary engineering analysis are virtually the same as those for design analysis. The primary difference is that planning and preliminary engineering analysis occurs very early in the process of project consideration.

The first criterion that categorizes such applications is the need to use more general estimates of input data. Many of the default values specified for freeway facilities in Chapter 10 would be applied. Alternatively, local default values can be substituted. Demand volumes might be specified only as expected values of annual average daily traffic (AADT) for a target year. Directional design-hour volumes are based on AADTs, default (local or global) values are used for the K-factor (the proportion of AADT occurring in the peak hour) and the D-factor (the proportion of peak hour traffic traveling in the peak direction). Guidance on these values is given in Chapter 3, Modal Characteristics.

On the basis of these default and estimated values, the analysis is conducted in the same manner as a design analysis.

Service Volumes and Service Flow Rates

The method can be applied to determine service volumes for LOS A–E for a specified set of conditions.

Service volume is the maximum hourly volume that can be accommodated without exceeding the limits of the various levels of service during the worst 15 min of the analysis hour. Service volumes can be found for LOS A–E. LOS F, which represents unstable flow, does not have a service volume.

Service flow rates are the maximum rates of flow (within a 15-min period) that can be accommodated without exceeding the limits of the various levels of service. As is the case for service volumes, service flow rates can be found for LOS A–E, but none is defined for LOS F. The relationship between service volume and service flow rate is as follows:

Equation 13-27

$$SV_i = SF_i \times PHF$$

where

SV_i = service volume for LOS i (pc/h),

SF_i = service flow rate for LOS i (pc/h), and

PHF = peak hour factor.

For ramp–freeway junctions, service flow rate or service volume could be defined in several ways. It might be argued that since ramp–freeway junction capacities are usually limited by the upstream or downstream freeway segment,

AR0073644

service flow rates and service volumes should be based on basic freeway criteria applied to the upstream or downstream freeway segments. This, however, would ignore the levels of service defined for the ramp influence area, which are the only unique service descriptors for ramps.

Levels of service for ramp–freeway junctions are defined in Exhibit 13-2 and relate to the density within the ramp influence area. The methodology estimates this density by using a series of algorithms affected by demand flows on the freeway, ramp, and adjacent ramps, ramp geometrics, and distances to adjacent ramps. The methodology uses demand volumes in vehicles per hour converted to demand flow rates in passenger cars per hour. Therefore, service flow rates and service volumes would originally be estimated in terms of flow rates in passenger cars per hour. They would then be converted back to demand volumes in vehicles per hour.

Because the balance of ramp and freeway demands has a significant impact on densities, there are a number of ways in which service flow rates and volumes can be considered:

- The limiting total upstream demand volume that produces a given LOS within the ramp influence area. The split between arriving freeway volume and ramp volume would have to be specified.
- The limiting volume entering the ramp influence area that produces a given LOS within the ramp influence area. Since this relies on the approaching freeway volume, the split between freeway and ramp demand would still have to be specified.
- The limiting ramp volume that produces a given LOS within the ramp influence area, based on a fixed upstream freeway demand.

Any of these are viable concepts for establishing a ramp service flow rate or service volume.

A number of factors influence the service volume to flow rate result, each of which must be individually considered.

In addition to different ways of interpreting a service volume or service flow rate, a large number of characteristics will influence the result, including the PHF, %HV, length of acceleration or deceleration lane(s), ramp FFS, and any relevant data for adjacent ramps. It is, therefore, virtually impossible to define a representative "typical" case with broadly applicable results. Each case must be individually considered.

The Example Problems section includes an example of how ramp junction service flow rates and service volumes can be computed.

USE OF ALTERNATIVE TOOLS

General guidance for the use of alternative traffic analysis tools for capacity and LOS analysis is provided in Chapter 6, HCM and Alternative Analysis Tools. This section contains specific guidance for applying alternative tools to the analysis of ramps and ramp junctions. Additional information on this topic may be found in the Volume 4 Technical Reference Library.

The HCM methodology for analyzing merge and diverge segments estimates the density of the ramp influence area (which includes the two rightmost lanes of the freeway and the acceleration or deceleration lane) and provides the

AR0073645

respective LOS. As an intermediate step, the methodology estimates the capacity at various points through the section, and if the capacity is exceeded, the LOS is determined to be F without further calculation of density. The methodology is primarily based on the estimation of the demand onto the influence area.

Strengths of the HCM Procedure

This chapter's procedures were developed on the basis of extensive research supported by a significant quantity of field data. They have evolved over a number of years and represent a body of expert consensus. Most simulation packages will not include the level of detail present in this methodology concerning the ramp itself and its adjacent upstream and downstream ramps.

The HCM procedure's strengths are as follows:

- The methodology provides capacity estimates. Simulators do not provide capacity estimates directly; they can be obtained by developing a data collection scheme in the simulator. Furthermore, the user can modify those simulated capacities by modifying specific input values, such as the minimum acceptable headway.
- The methodology explicitly considers the impacts of the presence of and demands on the upstream and downstream ramps.
- It produces a single deterministic estimate of density, which is important for some purposes, such as development impact review.

Limitations of the HCM Procedures That Might Be Addressed by Alternative Tools

A list of the HCM's limitations for freeway merge and diverge segments is provided in Exhibit 13-20.

Exhibit 13-20
Limitations of the HCM Ramps and Ramp Junctions Procedure

Limitation	Potential for Improved Treatment by Alternative Tools
Managed lanes, such as HOV lanes, as ramp entrance lanes	Modeled explicitly by simulation
Ramp metering	Modeled explicitly by simulation
Oversaturated conditions *(Refer to Chapter 10 for further discussion)*	Modeled explicitly by simulation
Posted speed limit and amount of police enforcement	Can be approximated by using assumptions related to the desired speed along a given segment
Presence of intelligent transportation system features	Several features modeled explicitly by simulation; others may be approximated by using assumptions (for example, by modifying origin–destination demands by time interval)
Freeway operational analysis beyond the 1,500-ft area of influence	Modeled explicitly by simulation
Capacity-enhancing effects of ramp metering	Can be approximated by using assumptions related to car-following, lane-changing, and gap-acceptance behavior

AR0073646

Ramp junctions can also be analyzed with a variety of stochastic and deterministic simulation packages that address freeways. These packages can be useful in analyzing the extent of congestion when there are failures either within or downstream of the simulated facility range.

Additional Features and Performance Measures Available From Alternative Tools

This chapter provides a methodology for estimating the capacity, speed, and density in the area of influence of on- and off-ramps, given traffic demands and segment characteristics. Alternative tools offer additional performance measures including delay, stops, queue lengths, fuel consumption, pollution, and operating costs.

As with most other HCM procedural chapters, simulation outputs, especially graphics-based presentations, can provide details on point problems that might otherwise go undetected with a macroscopic analysis that yields only segment-level measures. The effects of downstream conditions on lane utilization and backup beyond the segment boundary is a good example of a situation that can benefit from the increased insight offered by a microscopic model.

Development of HCM-Compatible Performance Measures Using Alternative Tools

The subject of performance-measure comparisons was discussed in more detail in Chapter 7, Interpreting HCM and Alternative Tool Results. This section deals with topics that apply specifically to ramps and ramp junctions.

When alternative tools are used, the analyst must be careful to note the definitions of simulation outputs. This chapter's measure of effectiveness for ramps and ramp junctions is the density of the ramp influence area. However, most simulators do not provide density estimates separately for the two right-most lanes within a link. This is a potentially significant obstacle in obtaining the service measures for ramp junctions from a simulator (unless the freeway has only two lanes per direction). Furthermore, at a simulator, there are lane changes along the entire segment. Therefore, it is not clear how a simulator should address the partial presence of vehicles in the link to ensure compatibility with the HCM. Also, as is generally the case for basic freeway segments, increased speed variability in driver behavior (which simulators usually include) results in lower average space mean speed and higher density.

Most simulation packages do not provide separate density estimates for the two right-most lanes within a link, which is a potentially significant obstacle in obtaining service measures.

In obtaining density from alternative models, it is important to consider the following:

- The ability of the simulator to provide density for the two rightmost lanes of the freeway;
- The vehicles included in the density estimation and how partial presence of vehicles on the link is considered;
- The manner in which the acceleration and deceleration lanes are considered in the density estimation;
- The units used by the simulator to measure density (most use vehicles rather than passenger cars); converting vehicles to passenger cars by using

AR0073647

the HCM's passenger-car equivalence (PCE) values is typically not appropriate, given that simulator assumptions with regard to heavy vehicle performance vary widely].

- The units used in the reporting of density (i.e., whether density is reported per lane or not);
- The homogeneity of the analysis segment in the simulator, as the HCM assumes conditions to be homogeneous unless it is a specific upgrade or downgrade segment, in which case the segment length is used to estimate the PCE values); and
- The treatment of driver variability by the simulator, as increased driver variability in the simulator will generally increase the average density.

With regard to capacity, the HCM provides capacity estimates in units of passenger cars per hour per lane as a function of FFS for the locations approaching and departing the merge junction. In comparing the HCM estimates with capacity estimates from a simulator, the following should be considered:

- The manner in which a simulator provides the number of vehicles exiting a segment. In some cases it may be necessary to provide "virtual" detectors at specific points on the simulated segment so that the maximum throughput can be obtained.
- The simulator provides the maximum throughput at a particular location in units of vehicles, rather than passenger cars. Converting these units to passenger cars by using the HCM's PCE values is typically not appropriate, given that simulator assumptions with regard to heavy vehicle performance vary widely.
- A simulator will likely include inputs such as the "minimum separation of vehicles," which greatly affects the maximum throughput.

Conceptual Differences Between the HCM and Simulation Modeling That Preclude Direct Comparison of Results

Ramp junction density does not change with FFS in the HCM method, but density is a function of FFS on most simulation roadways.

In the HCM, the density at a ramp junction does not change with FFS, although density drops as a function of FFS on basic freeway segments. In simulators, the density typically changes as a function of FFS (or the desired speed). Therefore, calibration of a site using a specific FFS does not necessarily ensure that the site will be calibrated for a different FFS. Capacity, on the other hand, increases in the HCM with increasing FFS, which is typically the case with simulators.

The HCM method is based on the estimated demand approaching the ramp influence area. This demand is estimated as a function of the presence of and demands on the upstream and downstream ramps. Traffic simulators do not typically allow the user to input the specific percentages of traffic on each lane at the beginning of a link. Their internal rules relative to the lane chosen by a vehicle in a given link vary widely and can be modified by changing various default values within the simulator. In some simulators, virtual vehicles are "aware" of their ultimate destination; in others, the exit choice is made on a link-by-link basis. However, in comparing HCM results with those of a simulator, the

AR0073648

analyst should, as an intermediate check, compare the flow approaching the two rightmost lanes of the junction.

Adjustment of Simulation Parameters to the HCM Results

The most important elements to be adjusted in analyzing a ramp junction are as follows:

- The flow approaching the two rightmost lanes (this is an intermediate step but would ensure that the influence of upstream and downstream ramps is considered in a manner compatible with the HCM), and
- The capacity of the junction at the critical locations indicated in the HCM (i.e., downstream of the junction and approaching the influence area).

Step-by-Step Recommendations for Applying Alternative Tools

The following steps are recommended when an alternative tool is applied to the analysis of ramps and ramp junctions.

1. Determine whether the chosen tool can provide density for the two rightmost lanes of the freeway and what approach is used to obtain it (including the treatment of the partial presence of vehicles on the link).
2. Determine the FFS of the study site, either from field data or by estimating it according to the Chapter 11 method for basic freeway segments.
3. Enter all available input characteristics (both geometric and traffic characteristics) into the simulator. The length of the segment or link to be simulated should be 1,500 ft, to correspond to the HCM-defined area of influence. Install virtual detectors within the area of influence and at the downstream end of the study segment to obtain density, speeds, and flows.
4. Load the study network above capacity to obtain the maximum throughput, and compare the result with the HCM estimate. Calibrate the simulator by modifying parameters related to the minimum time headway so that the simulated capacity matches the HCM estimate. Estimate the required number of simulation runs that will need to be conducted to produce a statistically valid comparison.
5. Compare the flow approaching the two rightmost lanes with the HCM's estimate. Adjust the simulation parameters related to driver awareness of upcoming lanes to match the HCM-predicted v_{12} value.

Example Problems Illustrating Alternative Tool Applications

Chapter 28, Freeway Merges and Diverges Supplemental, includes two example problems that examine situations beyond the scope of this chapter's methodology by using a typical microsimulation-based tool. Both problems are based on this chapter's Example Problem 3, which analyzes an eight-lane freeway segment with an entrance and an exit ramp. The first problem evaluates the effects of the addition of ramp metering, while the second evaluates the impacts of converting the leftmost lane of the mainline into an HOV lane.

AR0073649

4. EXAMPLE PROBLEMS

Exhibit 13-21
List of Example Problems

Example Problem	Title	Type of Analysis
1	Isolated One-Lane, Right-Hand On-Ramp to a Four-Lane Freeway	Operational analysis
2	Two Adjacent Single-Lane, Right-Hand Off-Ramps on a Six-Lane Freeway	Operational analysis
3	One-Lane On-Ramp Followed by a One-Lane Off-Ramp on an Eight-Lane Freeway	Operational analysis
4	Single-Lane, Left-Hand On-Ramp on a Six-Lane Freeway	Special case
5	Service Flow Rates and Service Volumes for an Isolated On-Ramp on a Six-Lane Freeway	Service flow rates and service volumes

EXAMPLE PROBLEM 1: ISOLATED ONE-LANE, RIGHT-HAND ON-RAMP TO A FOUR-LANE FREEWAY

The Facts

The following data are available to describe the traffic and geometric characteristics of this location:

- Isolated location (no adjacent ramps to consider)
- One-lane ramp roadway and junction
- Four-lane freeway (two lanes in each direction)
- Upstream freeway demand volume = 2,610 veh/h
- Ramp demand volume = 550 veh/h
- 10% trucks, 0% RVs on the freeway
- 5% trucks, 0% RVs on the ramp
- Acceleration lane = 240 ft
- FFS, freeway = 60 mi/h
- FFS, ramp = 45 mi/h
- Level terrain for freeway and ramp
- Peak hour factor = 0.90
- Drivers are regular commuters

Comments

All input parameters are known, so no default values are needed or used. Adjustment factors for heavy vehicles and driver population are found in Chapter 11, Basic Freeway Segments.

Step 1: Convert Demand Volumes to Flow Rates Under Equivalent Ideal Conditions by Using Equation 13-1

$$v = \frac{V}{PHF \times f_{HV} \times f_p}$$

AR0073650

Demand volumes are given for the freeway and the ramp. The PHF is specified. The driver population factor for commuters is 1.00 (Chapter 11), while the heavy vehicle adjustment factor is computed as follows:

$$f_{HV} = \frac{1}{1 + P_T(E_T - 1) - P_R(E_R - 1)}$$

Truck and RV presence is given. The value of E_T for level terrain is 1.5 (Chapter 11). On the basis of these values, the freeway and ramp demand volumes are converted as follows:

For the freeway:

$$f_{HV} = \frac{1}{1 + 0.10\,(1.5 - 1)} = 0.952$$

$$v_i = \frac{2{,}500}{0.90 \times 0.952 \times 1.00} = 2{,}918 \text{ pc/h}$$

For the ramp:

$$f_{HV} = \frac{1}{1 + 0.05\,(1.5 - 1)} = 0.976$$

$$v_i = \frac{550}{0.90 \times 0.976 \times 1.00} = 626 \text{ pc/h}$$

Step 2: Compute Demand Flow in Lanes 1 and 2 Immediately Upstream of the Ramp Influence Area with Equation 13-2 and Exhibit 13-6

$$v_{12} = v_i \times P_{FM}$$

The freeway flow rate was computed in Step 1. The value of P_{FM} is found in Exhibit 13-6. For a four-lane freeway, the value is 1.00. Then:

$$v_{12} = 2{,}918 \times 1.00 = 2{,}918 \text{ pc/h}$$

Because there are no auxiliary lanes on a four-lane freeway, there is no need to check this result for reasonableness.

Step 3: Check Capacities by Using Exhibit 13-8 and Exhibit 13-10

The critical capacity checkpoint for a single-lane on-ramp is the downstream freeway segment:

$$v_{FO} = v_i + v_R = 2{,}918 + 626 = 3{,}544 \text{ pc/h}$$

The capacity of a four-lane freeway (two lanes in one direction) with an FFS of 60 mi/h is given in Exhibit 13-8. The capacity is 4,600 pc/h, which is more than the demand flow of 3,544 pc/h. The capacity of a one-lane ramp with an FFS of 45 mi/h is given in Exhibit 13-10 as 2,000 pc/h, which is well in excess of the ramp demand flow of 626 pc/h. The maximum desirable flow rate entering the ramp influence area is also 4,600 pc/h, again more than 3,544. Thus, the operation of the segment is expected to be stable. LOS F does not exist.

AR0073651

Step 4: Compute Density and Find LOS by Using Equation 13-21 and Exhibit 13-2

The estimated density in the ramp–freeway junction is estimated by using Equation 13-21:

$$D_R = 5.475 + 0.00734v_{12} + 0.0078v_{34} - 0.00627L_A$$

$$D_R = 5.475 + (0.00734 \times 626) + (0.00078 \times 2{,}918) - (0.00627 \times 740) = 25.2 \text{ pc/mi/ln}$$

From Exhibit 13-2, this is LOS D, but the result is close to the LOS C boundary.

Step 5: Compute Merge Area Speed as Supplemental Information by Using Exhibit 13-11

Since there are no auxiliary lanes present on a four-lane freeway, only the speed within the ramp influence area should be computed:

$$S_R = FFS - (FFS - 42)M_s$$

$$M_s = 0.321 + 0.0039e^{-20.1(L_A S_{FR}/1{,}000)} - 0.002(L_A S_{FR}/1{,}000)$$

$$M_s = 0.321 + 0.0039e^{-20.1(740 \times 45/1{,}000)} - 0.002(740 \times 45/1{,}000) = 0.389$$

$$S_R = 60 - (60 - 42) \times 0.389 = 53.0 \text{ mi/h}$$

Discussion

The results indicate that the merge area operates in a stable fashion, with some deterioration in density and speed due to merging operations.

EXAMPLE PROBLEM 2: TWO ADJACENT SINGLE-LANE, RIGHT-HAND OFF-RAMPS ON A SIX-LANE FREEWAY

The Facts

The following information concerning demand volumes and geometrics is available for this problem:

- Two consecutive one-lane, right-hand off-ramps
- Six-lane freeway with FFS = 60 mi/h
- Rolling terrain for freeway and both ramps
- 5% trucks on freeway and both ramps; 0% RVs
- First ramp FFS = 40 mi/h
- Second ramp FFS = 25 mi/h
- Drivers are regular commuters
- Freeway demand volume = 4,500 veh/h (immediately upstream of the first off-ramp)
- First ramp demand volume = 300 veh/h
- Second ramp demand volume = 500 veh/h
- Distance between ramps = 750 ft
- First ramp deceleration lane length = 500 ft

AR0073652

- Second ramp deceleration lane length = 300 ft
- Peak hour factor = 0.95

Comments

The solution will use adjustment factors for heavy vehicle presence and driver population selected from Chapter 11, Basic Freeway Segments. All input parameters are specified, so no default values are needed or used.

Step 1: Convert Demand Volumes to Flow Rates Under Equivalent Ideal Conditions by Using Equation 13-1

$$v = \frac{V}{PHF \times f_{HV} \times f_p}$$

In this case, three demand volumes must be converted: the freeway volume immediately upstream of the first ramp and the two ramp demand volumes. Since all demands include 5% trucks and no RVs, only a single heavy vehicle adjustment factor will be needed. From Chapter 11, the appropriate value of E_T for rolling terrain is 2.5. For drivers who are regular commuters, the appropriate value of f_p is 1.00.

Then

$$f_{HV} = \frac{1}{1 + P_T(E_T - 1) + P_R(E_R - 1)}$$

$$f_{HV} = \frac{1}{1 + 0.05(2.5 - 1)} = 0.930$$

and

$$v = \frac{V}{PHF \times f_{HV} \times f_p}$$

$$v_1 = \frac{4,500}{0.95 \times 0.930 \times 1.00} = 5,093 \text{ pc/h}$$

$$v_{r1} = \frac{300}{0.95 \times 0.930 \times 1.00} = 340 \text{ pc/h}$$

$$v_{r2} = \frac{500}{0.95 \times 0.930 \times 1.00} = 566 \text{ pc/h}$$

Step 2: Compute Demand Flow in Lanes 1 and 2 Immediately Upstream of the Two Ramp Influence Areas by Using Equation 13-13 and Exhibit 13-7

Because there are two consecutive off-ramps under consideration, the first will have to consider the impact of the second on its operations, and the second will have to consider the impact of the first.

AR0073653

First Off Ramp

From Exhibit 13-7, flow in Lanes 1 and 2 of the freeway is estimated by using Equation 13-11 or Equation 13-9, depending on whether the impact of the downstream off-ramp is significant. This is determined by comparing the equivalence distance by using Equation 13-13:

$$L_{EQ} = \frac{v_{12}}{1.15 + 0.000032v_3 - 0.000369v_R}$$

$$L_{EQ} = \frac{566}{1.15 - (0.000032 \times 5{,}093) - (0.000369 \times 340)} = 657 \text{ ft}$$

Since the actual distance between ramps, 750 ft, is greater than the equivalence distance of 657 ft, the ramp may be treated as if it were isolated, with Equation 13-9:

$$P_{FM} = 0.760 - 0.000025v_3 - 0.000046v_R$$

$$P_{FM} = 0.760 - (0.000025 \times 5093) - (0.000046 \times 340) = 0.617$$

Then

$$v_{12} = v_R + (v_3 - v_R)P_{FM}$$

$$v_{12} = 340 + (5{,}093 - 340) \times 0.617 = 3{,}273 \text{ pc/h}$$

Because a six-lane freeway includes one outer lane (Lane 6), the reasonableness of the predicted lane distribution of arriving freeway vehicles should be checked. The flow rate in Lane 3 is 5,093 – 3,273 = 1,820 pc/h. The average flow per lane in Lanes 1 and 2 is 3,273/2 = 1,637 pc/h (rounded to the nearest pc). Then:

Is $v_3 > 2{,}700$ pc/h/ln? **No**

Is $v_3 > 1.5 \times (1{,}637) = 2{,}456$ pc/h/ln? **No**

Since both checks for reasonable lane distribution are passed, the computed value of v_{12} for the first off-ramp is accepted as 3,273 pc/h.

Second Off-Ramp

From Exhibit 13-7, the second off-ramp should be analyzed by using Equation 13-9, which is for an isolated off-ramp. Adjacent upstream off-ramps do not affect the lane distribution of arriving vehicles at a downstream off-ramp.

The freeway flow approaching Ramp 2, however, includes the freeway flow approaching Ramp 1, less the flow rate of vehicles exiting the freeway at Ramp 1. Therefore, the freeway flow rate approaching Ramp 2 is as follows:

$$v_3 = 5{,}093 - 340 = 4{,}753 \text{ pc/h}$$

Then

$$P_{FM} = 0.760 - (0.000025 \times 4753) - (0.000046 \times 566) = 0.615$$

$$v_{12} = 566 + (4{,}753 - 566) \times 0.615 = 3{,}141 \text{ pc/h}$$

AR0073654

Again, because there is an outer lane on a six-lane freeway, the reasonableness of this estimate must be checked. The flow rate in the outer lane (v_3) is 4,753 − 3,141 = 1,612 pc/h. The average flow rate in Lanes 1 and 2 is 3,141/2 = 1,571 pc/h/ln (rounded). Then

Is $v_3 > 2{,}700$ pc/h/ln?	No
Is $v_3 > 1.3 \times 1{,}571 = 2{,}357$ pc/h/ln?	No

Once again, the predicted lane distribution of arriving vehicles is reasonable, and v_{12} is taken to be 3,141 pc/h.

Step 3: Check Capacities by Using Exhibit 13-8 and Exhibit 13-10

Because two off-ramps are involved in this segment, there are several capacity checkpoints:

- Total freeway flow upstream of the first off-ramp (the point at which maximum freeway flow exists),
- Capacity of both off-ramps, and
- Maximum desirable flow rates entering each of the two off-ramp influence areas.

These comparisons are shown in Exhibit 13-22. Note that freeway capacity is based on a freeway with FFS = 60 mi/h. The first ramp capacity is based on a ramp FFS of 40 mi/h and the second on a ramp FFS of 25 mi/h.

Exhibit 13-22
Capacity Checks for Example Problem 2

Item	Capacity (pc/h) Exhibit 13-8, Exhibit 13-10	Demand Flow Rate (pc/h)	Problem?
Freeway flow rate	6,900	5,053	No
First off-ramp	2,000	340	No
Second off-ramp	1,900	586	No
Max. v, first ramp	4,400	3,377	No
Max. v, second ramp	4,400	3,141	No

None of the capacity values are exceeded, so operation of these ramp junctions will be stable, and LOS F does not occur.

Step 4: Compute Densities and Find Levels of Service by Using Equation 13-22 and Exhibit 13-2

Because there are two off-ramps, two ramp influence areas are involved, and two ramp influence area densities will be computed.

$$D_R = 4.252 + 0.0086 v_{12} - 0.009 L_a$$

$$D_{R1} = 4.252 + (0.0086 \times 3{,}273) - (0.009 \times 800) = 27.9 \text{ pc/mi/ln}$$

$$D_{R2} = 4.252 + (0.0086 \times 3{,}141) - (0.009 \times 300) = 28.6 \text{ pc/mi/ln}$$

From Exhibit 13-2, both of these ramp influence areas operate very close to the boundary between LOS C and LOS D (28.0 pc/mi/ln). Ramp 1 operates in LOS C, while Ramp 2 operates in LOS D.

While it makes virtually no difference in this case, note that the two ramp influence areas overlap. The influence area of the first off-ramp extends 1,500 ft upstream. The influence area of the second off-ramp also extends 1,500 ft

AR0073655

upstream. Given that the ramps are only 750 ft apart, the second ramp influence area overlaps the first for 750 ft (immediately upstream of the first diverge point). Normally, the worse of the two levels of service would be applied to this 750 ft overlap. In this case, the levels of service are the same. Indeed, the predicted densities are virtually equal, so the impact of the overlap is minimal, and the predicted values are not really affected.

Step 5: Compute Diverge Area Speeds as Supplemental Information by Using Exhibit 13-12 and Exhibit 13-13

Because these ramps are on a six-lane freeway with an outer lane, it is possible to estimate the speed within each ramp influence area, the speed in the outer lane adjacent to each ramp influence area, and the weighted average of the two.

First Off-Ramp

The speed within the first ramp influence area is computed as follows:

$$D_R = 0.883 + 0.00309 v_p - 0.013 S_{FO}$$

$$D_R = 0.883 + (0.00309 \times 3{,}273) - (0.013 \times 40) = 0.894$$

$$S_R = FFS - (FFS - 42) D_R = 60 - (60 - 42) \times 0.894 = 52.9 \text{ mi/h}$$

The flow rate in the outer lane (v_{o1}) is 5,093 − 3,273 = 1,820 pc/h/ln. The average speed in this outer lane is computed as follows:

$$S_{o1} = 1.097 FFS - 0.0039 (v_{o1} - 1{,}000)$$

$$S_{o1} = (1.097 \times 60) - 0.0039 \times (1{,}820 - 1{,}000) = 62.6 \text{ mi/h}$$

The average speed in Lane 3 is predicted to be slightly higher than the FFS of the freeway. This is not uncommon, since through vehicles at higher speeds use Lane 3 to avoid congestion in the ramp influence area. The average speed across all lanes, however, should not be higher than the FFS. In this case, the average speed across all lanes is computed as follows:

$$S = \frac{3{,}273 + (1{,}820 \times 1)}{\left(\frac{3{,}273}{52.9}\right) + \left(\frac{1{,}820 \times 1}{62.0}\right)} = 56.0 \text{ mi/h}$$

This result is, as expected, less than the FFS of the freeway.

Second Off-Ramp

The speed in the second ramp influence area is computed as follows:

$$D_R = 0.883 + (0.00309 \times 566) - (0.013 \times 25) = 0.889$$

$$S_R = 60 - (60 - 42) \times 0.889 = 49.0 \text{ mi/h}$$

Lane 3 has a demand flow rate of 4,753 − 3,141 = 1,612 pc/h/ln. The average speed in the outer lane is computed as follows:

$$S_{o2} = (1.097 \times 60) - 0.0039 \times (1{,}612 - 1{,}000) = 63.4 \text{ mi/h}$$

The average speed across all freeway lanes is

AR0073656

$$S = \frac{3{,}141 - (1{,}612 \times 1)}{\left(\frac{3{,}141}{49.0}\right) + \left(\frac{1{,}612 \times 1}{63.4}\right)} = 53.1 \text{ mi/h}$$

Discussion

The speed results in this case are interesting. While densities are similar for both ramps, the density is somewhat higher and the speed somewhat lower in the second influence area. This is primarily the result of a shorter deceleration lane and a lower ramp FFS (25 mi/h versus 40 mi/h). In both cases, the average speed in the outer lane is higher than the FFS, which applies as an average across all lanes.

Since the operation is stable, there is an special concern here, short of a significant increase in demand flows. LOS is technically D but falls just over the LOS C boundary. This is a case in which the step function LOS assigned may imply an operation poorer than actually exists. It emphasizes the importance of knowing not only the LOS but also the value of the service measure that predicates it.

EXAMPLE PROBLEM 3: ONE-LANE ON-RAMP FOLLOWED BY A ONE-LANE OFF-RAMP ON AN EIGHT-LANE FREEWAY

The Facts

The following information is available concerning this pair of ramps to be analyzed:

- Eight-lane freeway with an FFS of 65 mi/h
- One-lane, right-hand on ramp with an FFS of 40 mi/h
- One-lane, right-hand off ramp with an FFS of 25 mi/h
- Distance between ramps = 1,300 ft
- Acceleration lane on Ramp 1 = 260 ft
- Deceleration lane on Ramp 2 = 260 ft
- Level terrain on freeway and both ramps
- 10% trucks, no RVs on freeway and off ramp
- 5% trucks, no RVs on on ramp
- Freeway flow rate (upstream of first ramp) = 5,500 veh/h
- On-ramp flow rate = 400 veh/h
- Off-ramp flow rate = 400 veh/h
- PHF = 0.90
- Drivers are regular commuters

Comments

As with previous example problems, the conversion of demand volumes to flow rates requires adjustment factors selected from Chapter 11, Basic Freeway

AR0073657

Segments. All pertinent information is given, and no default values will be applied.

Step 1: Convert Demand Volumes to Flow Rates Under Equivalent Ideal Conditions by Using Equation 13-1

$$v = \frac{V}{PHF \times f_{HV} \times f_p}$$

Three demand volumes must be converted to flow rates under equivalent ideal conditions: the freeway volume immediately upstream of the first ramp junction, the first ramp volume, and the second ramp volume. Because the freeway segment under study has level terrain, the value of E_T will be 1.5 for all volumes. Because the drivers are regular commuters, the driver population factor, f_p, is 1.00.

Then, for the freeway demand volume:

$$f_{HV} = \frac{1}{1 + 0.10(1.5 - 1)} = 0.952$$

$$v_F = \frac{5{,}500}{0.90 \times 0.952 \times 1.00} = 6{,}419 \text{ pc/h}$$

For the on-ramp demand volume:

$$f_{HV} = \frac{1}{1 + 0.05(1.5 - 1)} = 0.976$$

$$v_{ON} = \frac{400}{0.90 \times 0.976 \times 1.00} = 455 \text{ pc/h}$$

For the off-ramp demand volume:

$$f_{HV} = \frac{1}{1 + 0.10(1.5 - 1)} = 0.952$$

$$v_{OF} = \frac{600}{0.90 \times 0.952 \times 1.00} = 700 \text{ pc/h}$$

In the remaining computations, these converted demand flow rates are used as input values.

Step 2: Compute Demand Flow in Lanes 1 and 2 Immediately Upstream of the Two Ramp Influence Areas by Using Equation 13-2 and Exhibit 13-6 for the On-Ramp and Equation 13-8 and Exhibit 13-7 for the Off-Ramp

Once again, the situation involves a pair of adjacent ramps. Each ramp must consider the potential impact of the other on its operations. Because the ramps are on an eight-lane freeway (four lanes in each direction), Exhibit 13-6 and Exhibit 13-7 indicate that each ramp is considered as if it were isolated.

AR0073658

First Ramp (On-Ramp)

Equation 13-2 and Exhibit 13-6 apply to on-ramps. Exhibit 13-6 presents two possible equations for use in estimating P_{FO} on the basis of the value of v_R/L_A. In this case, the value is 6,419/3,000 = 2,106 > 72. Therefore, Equation 13-3 is used, giving the following.

$$v_{12} = v_F \times P_{FO}$$

$$P_{FO} = 0.2178 - 0.000125 v_R$$

$$P_{FO} = 0.2178 - (0.000125 \times 455) = 0.161$$

$$v_{12} = 6,429 \times 0.161 = 2,033 \text{ pc/h}$$

Because the eight-lane freeway includes two outer lanes in each direction, the reasonableness of this prediction must be checked. The average flow per lane in Lanes 1 and 2 is 2,033/2 = 817 pc/h/ln (rounded). The flow in the two outer lanes, Lanes 3 and 4, is 6,419 − 2,033 = 5,486 pc/h. The average flow per lane in Lanes 3 and 4 is, therefore, 5,386/2 = 2,693 pc/h/ln. Then:

Is $v_{FO} > 2,700$ pc/h/ln? No

Is $v_{FO} > 1.5 \times 817 = 1,226$ pc/h/ln? Yes

The predicted lane distribution, therefore, is not reasonable. Too many vehicles are placed in the two outer lanes compared with Lanes 1 and 2. Equation 13-19 is used to produce a more reasonable distribution:

$$v_{12} = \begin{pmatrix} v_1 \\ 2,500 \end{pmatrix} = \begin{pmatrix} 6,419 \\ 2,500 \end{pmatrix} = 2,568 \text{ pc/h}$$

On the basis of this adjusted value, the number of vehicles now assigned to the two outer lanes is 6,419 − 2,568 = 3,851 pc/h.

Second Ramp (Off Ramp)

Equation 13-8 and Exhibit 13-7 apply to off-ramps. Exhibit 13-7 shows that the value of P_{FO} for off-ramps on eight-lane freeways is a constant: 0.436. As the methodology is based on regression analyses of a database, the recommendation of a constant reflects a small sample size in that database. Note also that the freeway flow approaching the second ramp is the sum of the freeway flow approaching the first ramp and the on-ramp flow that is now also on the freeway, or 6,419 + 455 = 6,874 pc/h. The flow rate in Lanes 1 and 2 is now easily computed by using Equation 13-8:

$$v_{12} = v_{ff} - (v_r - v_R) P_{FO}$$

$$v_{12} = 700 + (6,874 - 700) \times 0.436 = 3,392 \text{ pc/h}$$

Because there are two outer lanes on this eight-lane freeway, the reasonableness of this estimate must be checked. The average flow per lane in Lanes 1 and 2 is 3,392/2 = 1,696 pc/h/ln. The total flow in Lanes 3 and 4 of the freeway is 6,874 − 3,392 = 3,482 pc/h, or an average flow rate per lane of 3,482/2 = 1,741 pc/h/ln.

Is $v_{FO} > 2,700$ pc/h/ln? No

AR0073659

Is $v_{12,EQ} > 1.5 \times 1,696 = 2,544$ pc/h/ln? No

Therefore, the estimated value of v_{12} is deemed reasonable and is carried forward in the computations.

Step 3: Check Capacities by Using Exhibit 13-8 and Exhibit 13-10

Because there are two ramps in this segment, there are five capacity checkpoints to consider:

- The freeway flow rate at its maximum point—which in this case is between the on- and off-ramp, since this is the only location where both on- and off-ramp vehicles are on the freeway.
- The capacity of the on-ramp.
- The capacity of the off-ramp.
- The maximum desirable flow entering the on-ramp influence area.
- The maximum desirable flow entering the off-ramp influence area.

These comparisons are shown in Exhibit 13-23. The capacity of the freeway is based on an eight-lane freeway with an FFS of 65 mi/h. The capacity of the on-ramp is based on an FFS of 50 mi/h, and the capacity of the off-ramp is based on an FFS of 55 mi/h.

Exhibit 13-23
Capacity Checks for Example Problem 3

Item	Capacity (pc/h) Exhibit 13-8, Exhibit 13-10	Demand Flow Rate (pc/h)	Problem?
Freeway flow rate	8,400	6,879	No
First on-ramp	1,900	345	No
Second off-ramp	1,900	700	No
Max. v_{12}, first ramp	4,600	2,568 + 455 = 3,023	No
Max. v_{12}, second ramp	4,400	3,392	No

There are no capacity concerns, since all demands are well below the associated capacities or maximum desirable values. LOS F is not present in any part of this segment, and operations are expected to be stable.

Step 4: Compute Densities and Find Levels of Service by Using Equation 13-21, Equation 13-22, and Exhibit 13-2

Equation 13-21 is used to find the density in the first on-ramp influence area.

$$D_R = 5.475 + 0.00734 v_R + 0.0078 v_{12} - 0.00627 L_A$$

$$D_R = 5.475 + (0.00734 \times 455) + (0.0078 \times 2,568) - (0.00627 \times 260) = 27.2 \text{ pc/mi/ln}$$

Equation 13-22 is used to find the density in the second off-ramp influence area.

$$D_R = 4.252 + 0.0086 v_{12} - 0.009 L_D$$

$$D_R = 4.252 + (0.0086 \times 3,391) - (0.009 \times 260) = 31.1 \text{ pc/mi/ln}$$

From Exhibit 13-2, both of these ramp influence areas operate very close to the boundary between LOS C and LOS D (28 pc/mi/ln). Ramp 1 operates in LOS C, while Ramp 2 operates in LOS D.

AR0073660

Because the on-ramp influence area extends 1,500 ft downstream, the off-ramp influence area extends 1,500 ft upstream, and the two ramps are only 1,300 ft apart, the distance between the ramps is included in both. Therefore, the more pessimistic prediction of 1.026 for the off-ramp governs the operation. Oddly, the additional 200 ft of the off-ramp influence area is actually upstream of the on-ramp, and the additional 200 ft of the on-ramp influence area is downstream of the off-ramp.

Step 5: Compute Merge and Diverge Area Speeds as Supplemental Information by Using Exhibit 13-11 and Exhibit 13-12

Because of the eight-lane freeway, speeds should be estimated for the two ramp influence areas, for the outer lanes (Lanes 3 and 4) adjacent to the ramp influence area, and for all vehicles—the weighted average of the other two speeds.

First Ramp (On Ramp)

Equations for estimation of average speed in an on-ramp influence area and in outer lanes adjacent to it are taken from Exhibit 13-11.

$$M_s = 0.321 + 0.0039e^{(v_o + 1.3v_r)} - 0.002(L_a S_{pd} / 1{,}000)$$

$$M_s = 0.321 + 0.0039e^{(3{,}032 + 1{,}926)/1{,}000} - 0.002(260/30) = 0.385$$

$$S_o = FFS - (FFS - 42)M_s = 65 - (65 - 42) \times 0.385 = 56.2 \text{ mi/h}$$

Since the average outer lane demand flow rate is 3,651/3 = 1,926 pc/h/ln, which is greater than 500 pc/h/ln and less than 2,300 pc/h/ln, the outer speed is estimated as follows:

$$S_{12} = FFS - 0.0036(v_{12} - 500)$$

$$S_{12} = 65 - 0.0036(1{,}926 - 500) = 59.9 \text{ mi/h}$$

The weighted average speed of all vehicles is

$$S = \frac{3{,}032 + (1{,}926 \times 2)}{\left(\frac{3{,}032}{56.2}\right) + \left(\frac{1{,}926 \times 2}{59.9}\right)} = 58.2 \text{ mi/h}$$

Second Ramp (Off-Ramp)

For off-ramps, equations for estimation of average speed are drawn from Exhibit 13-12. At the second ramp, the flow in Lanes 1 and 2 has been computed as 3,392 pc/h or 1,696 pc/h/ln, while the flow in Lanes 3 and 4 is 3,482 pc/h or 1,741 pc/h/ln. Then

$$D_s = 0.883 - 0.00009v_o + 0.013S_{12}$$

$$D_s = 0.883 + (0.00009 \times 700) - (0.013 \times 25) = 0.621$$

$$S_o = FFS - (FFS - 42)D_s$$

$$S_o = 65 - (65 - 42) \times 0.621 = 50.7 \text{ mi/h}$$

AR0073661

Because the average flow in the outer lanes is greater than 1,000 pc/h/ln, the average speed of vehicles in the outer lanes (Lanes 3 and 4) is as follows:

$$S_o = 1.097FFS - 0.0039(v_{p,o} - 1{,}000)$$

$$S_o = (1.097 \times 65) - 0.0039(1{,}741 - 1{,}000) = 68.4 \text{ mi/h}$$

The weighted average speed of all vehicles is

$$S = \frac{3{,}392 + (1{,}741 \times 2)}{\left(\frac{3{,}392}{50.7}\right) + \left(\frac{1{,}741 \times 2}{68.4}\right)} = 58.3 \text{ mi/h}$$

Discussion

As noted previously, between the ramps, the influence areas of both ramps fully overlap. Since a higher density is predicted for the off-ramp influence area, and LOS D results, this density would be applied to the entire area between the two ramps.

The speed results are also interesting. The slower speeds within the off-ramp influence area will also control the overlap area. On the other hand, the speed results indicate a higher average speed for all vehicles associated with the off-ramp than the speed associated with the on-ramp. This is primarily due to the much larger disparity between speeds within the ramp influence area and in outer lanes when the off-ramp is considered. The speed differential is more than 20 mi/h for the off-ramp, as opposed to a little more than 3 mi/h for the on-ramp. This is not entirely unexpected. At diverge junctions, vehicles in outer lanes tend to face less turbulence than those in outer lanes near merge junctions. All off-ramp vehicles must be in Lanes 3 and 4 for some distance before exiting the freeway. On-ramp vehicles, on the other hand, can execute as many lane changes as they wish—consistent with safety and sanity—and more of them may wind up in outer lanes within 1,500 ft of the junction point.

Thus, the total operation of this two-ramp segment is expected to be LOS D, with speeds of approximately 50 mi/h in Lanes 1 and 2 and approximately 70 mi/h in Lanes 3 and 4.

EXAMPLE PROBLEM 4: SINGLE-LANE, LEFT-HAND ON-RAMP ON A SIX-LANE FREEWAY

The Facts

- One-lane, left-side on-ramp on a six-lane freeway (three lanes in each direction)
- Freeway demand volume upstream of ramp = 4,600 veh/h
- On-ramp demand volume = 500 veh/h
- 25% trucks, no RVs on freeway
- 5% trucks, no RVs on ramp
- Freeway FFS = 65 mi/h
- Ramp FFS = 30 mi/h

AR0073662

- Accelerations are 820 ft
- Level terrain on freeway and ramp
- Drivers are regular commuters

Comments

This is a special application of the ramp analysis methodology presented in this chapter. For left hand ramps, the flow rate in Lanes 1 and 2 (v_{12}) is initially computed as if it were a right hand ramp. Exhibit 13-16 is then used to convert this result to an estimate of the flow in Lanes 2 and 3 (v_{23}), since these are the two leftmost lanes that will be traversed in the merge. In effect, the ramp influence area is, in this case, Lanes 3 and 4 and the acceleration lane for a distance of 1,500 ft downstream of the merge point.

Step 1: Convert Demand Volumes to Flow Rates Under Equivalent Ideal Conditions by Using Equation 13-1

$$v = \frac{V}{PHF \times f_{HV} \times f_p}$$

From Chapter 11, Basic Freeway Segments, the passenger car equivalent E_T for trucks in level terrain is 1.5. The driver population adjustment factor f_p for regular commuters is 1.00.

For the freeway demand volume:

$$f_{HV} = \frac{1}{1 + P_T(E_T - 1)} = \frac{1}{1 + 0.15(1.5 - 1)}$$

$$f_{HV} = 0.930$$

$$v_F = \frac{4{,}089}{0.90 \times 0.93 \times 1.00} = 4{,}779 \text{ pc/h}$$

For the ramp demand volume:

$$f_{HV} = \frac{1}{1 + 0.05(1.5 - 1)} = 0.976$$

$$v_R = \frac{500}{0.90 \times 0.976 \times 1.00} = 569 \text{ pc/h}$$

Step 2: Compute Demand Flow in Lanes 2 and 3 Immediately Upstream of the Ramp Influence Area by Using Equation 13-2 and Exhibit 13-6

To estimate flow in the two left lanes, the flow normally expected in Lanes 1 and 2 for a similar right hand ramp must first be computed. From Exhibit 13-6, for an isolated on-ramp on a six-lane freeway, Equation 13-4 is used.

$$v_{12} = v_i \times P_{FM}$$

$$P_{FM} = 0.5775 + 0.000028L_A$$

AR0073663

$$P_{FM} = 0.5775 + (0.000028 \times 820) = 0.601$$

$$v_{12} = 4,779 \times 0.601 = 2,867 \text{ pc/h}$$

From Exhibit 13-16, the adjustment factor applied to this result to find the estimated flow rate in Lanes 2 and 3 is 1.12. Therefore:

$$v_{23} = 2,867 \times 1.12 = 3,211 \text{ pc/h}$$

While, strictly speaking, the reasonableness criteria for lane distribution do not apply to left-hand ramps, they can be applied very approximately. In this case, the single "outer lane" (which is now Lane 1) would have a flow rate of $4,779 - 3,211 = 1,568$ pc/h. This is not greater than 2,700 pc/h/ln, nor is it greater than 1.5 times the average flow in Lanes 2 and 3 ($1.5 \times 3,211/2 = 2,408$ pc/h/ln). Thus, even if the reasonableness criteria were approximately applied in this case, no violation would exist.

The remaining computations proceed for the left-hand ramp, with the substitution of v_4 for v_3 in the algorithm used.

Step 3: Check Capacities by Using Exhibit 13-8 and Exhibit 13-10

For this case, there are three simple checkpoints:

- The principal capacity checkpoint is the total demand flow rate downstream of the merge, $4,779 + 569 = 5,348$ pc/h. From Exhibit 13-8, for a six-lane freeway with an FFS of 65 mi/h, the capacity is 7,050 pc/h, well over the demand flow rate.
- The ramp roadway capacity should also be checked by using Exhibit 13-10. For a single-lane ramp with an FFS of 30 mi/h, the capacity is 1,900 pc/h, which is much greater than the demand flow rate of 569 pc/h.
- Finally, the maximum flow entering the ramp influence area should be checked. In this case, a left-hand ramp, the total flow entering the ramp influence area is the freeway flow remaining in Lanes 2 and 3 plus the ramp flow rate. Thus, the total flow entering the ramp influence area is $3,211 + 569 = 3,780$ pc/h, which is lower than the maximum desirable flow rate of 4,600 pc/h, shown in Exhibit 13-8.

Thus, there are no capacity problems at this merge point, and stable operations are expected. LOS F will not result from the stated conditions.

Step 4: Compute Densities and Find Levels of Service by Using Equation 13-21 and Exhibit 13-2

The density in the ramp influence area is found by using Equation 13-21, except v_4 replaces v_R because of the left-hand ramp placement:

$$D_I = 5.475 + 0.00734\,v_4 - 0.00978\,v_{23} + 0.000627\,L_A$$

$$D_I = 5.475 + (0.00734 \times 569) - (0.00978 \times 3,211) + (0.000627 \times 820) = 29.6 \text{ pc/mi/ln}$$

From Exhibit 13-2, this is LOS D.

AR0073664

Step 5: Compute Merge and Diverge Area Speeds as Supplemental Information by Using Exhibit 13-11 and Exhibit 13-13

The speed estimation algorithms were calibrated for right-hand ramps, and the estimation algorithms for "outer lane(s)" assume that these are the leftmost lanes. Thus, for a left-hand ramp, these computations must be considered approximate at best.

By using the equations in Exhibit 13-11 and Exhibit 13-13, the following results are obtained:

$$M1_o = 0.321 + 0.0039e^{(-0.0021 \times 1{,}000)} - 0.002(820 \times 30 / 1{,}000) = 0.443$$

$$S_o = 65 - (65 - 42) \times 0.443 = 54.8 \text{ mi/h}$$

$$S_i = 65 - 0.0036\,(1{,}568 - 500) = 61.2 \text{ mi/h}$$

$$S = \frac{3{,}780 + (1{,}568 \times 1)}{\left(\frac{3{,}780}{54.8}\right) + \left(\frac{1{,}568 \times 1}{61.2}\right)} = 56.5 \text{ mi/h}$$

While traffic in the outer lane is predicted to travel somewhat faster than traffic in the lanes in the ramp influence area (which includes the acceleration lane), the approximate nature of the speed result for left-hand ramps makes it difficult to draw any firm conclusions concerning speed behavior.

Discussion

This example problem is typical of the way the situations in the Special Cases section are treated. Modifications as specified are applied to the standard algorithms used for single-lane, right-hand ramp junctions. In this case, operations are acceptable, but in LOS D—though not far from the LOS C boundary. Because the left-hand lanes are expected to carry freeway traffic flowing faster than right-hand lanes, right-hand ramps are normally preferable to left-hand ramps when they can be provided without great difficulty.

EXAMPLE PROBLEM 5: SERVICE FLOW RATES AND SERVICE VOLUMES FOR AN ISOLATED ON-RAMP ON A SIX-LANE FREEWAY

The Facts

The following facts have been established for this situation:

- Single-lane, right-hand on-ramp with an FFS of 40 mi/h
- Six-lane freeway (three lanes in each direction) with an FFS of 70 mi/h
- Level terrain for freeway and ramp
- 12% trucks, 3% RVs on freeway
- 5% trucks, 2% RVs on ramp
- Peak hour factor = 0.97
- Drivers are regular users of the facility
- Acceleration lane = 1,000 ft

AR0073665

Comments

This example illustrates the computation of service flow rates and service volumes for a ramp–freeway junction. The case selected is relatively straightforward to avoid cluttering the illustration with extraneous complications that have been addressed in other example problems.

Two approaches will be demonstrated:

1. The ramp demand flow rate will be stated as a fixed percentage of the arriving freeway flow rate. The service flow rates and service volumes are expressed as arriving freeway flow rates that result in the threshold densities within the ramp influence area that define the limits of the various levels of service. For this computation, the ramp flow is set at 10% of the approaching freeway flow rate.
2. A fixed freeway demand flow rate will be stated, with service flow rates and service volumes expressed as ramp demand flow rates that result in the threshold densities within the ramp influence area that define the limits of the various levels of service. For this computation, the approaching freeway flow rate is set at 4,000 veh/h.

For LOS E, density does not define the limiting value of service flow rate, which is analogous to capacity for ramp–freeway junctions. It is defined as the flow that results in capacity being reached on the downstream freeway segment or ramp roadway.

Since all algorithms in this methodology are calibrated for passenger cars per hour under equivalent ideal conditions, initial computations are made in those terms. Results are then converted to service flow rates by using the appropriate heavy vehicle and driver population adjustment factors. Service flow rates are then converted to service volumes by multiplying by the peak hour factor.

From Exhibit 13-2, the following densities define the limits of LOS A–D:

LOS A	10 pc/mi/ln
LOS B	20 pc/mi/ln
LOS C	28 pc/mi/ln
LOS D	35 pc/mi/ln

From Exhibit 13-8 and Exhibit 13-10, capacity (or the threshold for LOS E) occurs when the downstream freeway flow rate reaches 7,200 pc/h (FFS = 70 mi/h) or when the ramp flow rate reaches 2,000 pc/h (ramp FFS = 40 mi/h).

Case 1: Ramp Demand Flow Rate = 0.10 Freeway Demand Flow Rate

Equation 13-21 defines the density at an on-ramp influence area as follows:

$$D_R = 5.475 + 0.00734 v_R + 0.0078 v_{FD} - 0.00627 L_A$$

In this case:

$v_R = 0.10 v_F$

$L_A = 1.0$ mi

Equation 13-2 and Exhibit 13-6 give the following:

AR0073666

$$v_{12} = v_f \times P_{FM}$$

$$P_{FM} = 0.5775 - 0.000028L_a$$

$$P_{FM} = 0.5775 - [0.000028 \times 1{,}000) \quad 0.6055$$

$$v_{12} \quad 0.6055v_f$$

Substitution of these values into Equation 13-21 gives:

$$D_R = 5.475 - [0.00734 \times 0.10v_r) + [0.00978 \times 0.6055v_f) - (0.00627 \times 1{,}000)$$

$$D_R = 5.475 + 0.000734v_r + 0.00592v_f - 6.27$$

$$D_R = 0.005454v_f \quad 0.795$$

$$v_f = \frac{D_R + 0.795}{0.005454}$$

This equation can now be solved for threshold values of v_f for LOS A through D by using the appropriate threshold values of density. The results will be in terms of service flow rates under equivalent ideal conditions:

$$v_f \text{ (LOS A)} = \frac{10 + 0.795}{0.005454} = 1{,}979 \text{ pc/h}$$

$$v_f \text{ (LOS B)} = \frac{20 + 0.795}{0.005454} = 3{,}813 \text{ pc/h}$$

$$v_f \text{ (LOS C)} = \frac{28 + 0.795}{0.005454} = 5{,}280 \text{ pc/h}$$

$$v_f \text{ (LOS D)} = \frac{35 + 0.795}{0.005454} = 6{,}563 \text{ pc/h}$$

At capacity, the limiting flow rate occurs when the downstream freeway segment is 7,200 pc/h. If the ramp flow rate is 0.10 of the approaching freeway flow rate, then

$$v_{12} = 7{,}200 = v_f + 0.10v_f \quad 1.10v_f$$

$$v_f \text{ (LOS E)} = \frac{7{,}200}{1.10} = 6{,}545 \text{ pc/h}$$

This must be checked to ensure that the ramp flow rate ($0.10 \times 6{,}545 = 655$ pc/h) does not exceed the ramp capacity of 2,000 pc/h. Since it does not, the computation stands.

Note, however, that the LOS E (capacity) threshold is lower than the LOS D threshold. This indicates that LOS D operation cannot be achieved at this location. Before densities reach the 35 pc/h/ln threshold for LOS D, the capacity of the merge junction has been reached. Thus, there is no service flow rate or service volume for LOS D.

The computed values, as noted, are in terms of passenger cars per hour under equivalent ideal conditions. To convert these to service flow rates in vehicles per hour under prevailing conditions, they must be multiplied by the

AR0073667

heavy vehicle adjustment factor and the driver population factor. The approaching freeway flow rate includes 12% trucks and 3% RVs. For level terrain (Chapter 11, Basic Freeway Segments), $E_T = 1.5$ and $E_R = 1.2$. Then

$$f_{HV} = \frac{1}{1 + 0.12(1.5 - 1) + 0.03(1.2 - 1)} = 0.938$$

The driver population factor f_p for regular facility users is 1.00. Service volumes are obtained by multiplying service flow rates by the specified PHF, 0.87. These computations are illustrated in Exhibit 13-24.

Exhibit 13-24
Illustrative Service Flow Rates and Service Volumes Based on Approaching Freeway Demand

LOS	Service Flow Rate, Ideal Conditions (pc/h)	Service Flow Rate, Prevailing Conditions (SF) (veh/h)	Service Volume (SV) (veh/h)
A	1,970	1,970 × 0.938 × 1 = 1,848	1,848 × 0.87 = 1,608
B	3,813	3,813 × 0.938 × 1 = 3,577	3,577 × 0.87 = 3,112
C	5,288	5,288 × 0.938 × 1 = 4,960	4,960 × 0.87 = 4,315
D	NA	NA	NA
E	6,545	6,545 × 0.938 × 1 = 6,138	6,138 × 0.87 = 5,341

The service flow rates and service volumes shown in Exhibit 13-24 are stated in terms of the approaching freeway demand.

Case 2: Approaching Freeway Demand Volume = 4,000 veh/h

In this case, the approaching freeway demand will be held constant, and service flow rates and service volumes will be stated in terms of the ramp demand that can be accommodated at each LOS.

Since the freeway demand is stated in terms of an hourly volume in mixed vehicles per hour, it will be converted to passenger cars per hour under equivalent ideal conditions for use in the algorithms of this methodology.

$$v_f = \frac{V_f}{PHF \times f_{HV} \times f_p} = \frac{4,000}{0.87 \times 0.938 \times 1} = 4,902 \text{ pc/h}$$

The density is estimated by using Equation 13-20, and the variable P_{FM}, which is not dependent on v_R, remains 0.6055 as in Case 1. With a fixed value of freeway demand:

$$v_{12} = 0.6055 \times 4,902 = 2,968 \text{ pc/h}$$

Then, by using Equation 13-21:

$$D_R = 5.475 + 0.00734 v_{12} + (0.0078 \times 2,968) - (0.00627 \times 1,000)$$

$$D_R = 22.355 + 0.00734 v_R$$

$$v_R = \frac{D_R - 22.355}{0.00734}$$

It is apparent from this equation that neither LOS A ($D_R = 10$ pc/mi/ln) nor LOS B ($D_R = 20$ pc/mi/ln) can be achieved with a fixed freeway demand flow of 4,902 pc/h.

For LOS C and D:

AR0073668

$$v_o(\text{LOS C}) = \frac{28 - 22.355}{0.00734} = 769 \text{ pc/h}$$

$$v_o(\text{LOS D}) = \frac{35 - 22.355}{0.00734} = 1{,}723 \text{ pc/h}$$

Capacity, the limit of LOS E, occurs when the downstream freeway flow reaches 7,200 pc/h. With a fixed freeway demand,

$$v_{fr} = 7{,}200 - 4{,}912 + v_o$$

$$v_o(\text{LOS E}) = 7{,}200 - 4{,}912 = 2{,}298 \text{ pc/h}$$

This, however, violates the capacity of the ramp roadway, which is 2,000 pc/h. Thus, the limiting ramp flow rate for LOS E is set at 2,000 pc/h.

As in Case 2, these values are all stated in terms of passenger cars per hour under equivalent ideal conditions. They are converted to service flow rates by multiplying by the appropriate heavy vehicle and driver population adjustment factors. Since the ramp has a composition different from that of the approaching freeway flow, its adjustment must be recomputed:

$$f_{HV} = \frac{1}{1 + 0.05(1.5 - 1) + 0.02(1.2 - 1)} = 0.972$$

Service flow rates are converted to service volumes by multiplying by the peak hour factor. These computations are illustrated in Exhibit 13-25.

LOS	Service Flow Rate, Ideal Conditions (pc/h)	Service Flow Rate, Prevailing Conditions (SF) (veh/h)	Service Volume (SV) (veh/h)
A	NA	NA	NA
B	NA	NA	NA
C	769	769 × 0.972 × 1 = 747	747 × 0.87 = 650
D	1,723	1,723 × 0.972 × 1 = 1,675	1,675 × 0.87 = 1,457
E	2,000	2,000 × 0.972 × 1 = 1,944	1,944 × 0.87 = 1,691

Exhibit 13-25
Illustrative Service Flow Rates and Service Volumes Based on a Fixed Freeway Demand

These service flow rates and service volumes are based on a constant upstream and ramp freeway demand and are stated in terms of limiting on-ramp demands for that condition.

Discussion

As this illustration shows, many considerations are involved in estimating service flow rates and service volumes for ramp–freeway junctions, not the least of which is specifying how such values should be defined. The concept of service flow rates and service volumes at specific ramp–freeway junctions is of limited utility. Since many of the details that affect the estimates will not be determined until final designs are prepared, operational analysis of the proposed design may be more appropriate.

Case 3 could have applications in considering ramp-to-ramp metering. Appropriate limiting ramp flows can be estimated by using the same approach as for service volumes and service flow rates.

1. INTRODUCTION

VOLUME 2: UNINTERRUPTED FLOW
10. Freeway Facilities
11. Basic Freeway Segments
12. Freeway Weaving Segments
13. Freeway Merge and Diverge Segments
14. Multilane Highways
15. Two-Lane Highways

Chapter 14, Multilane Highways, addresses capacity and level-of-service (LOS) analysis for uninterrupted-flow segments of surface multilane highways. In general, uninterrupted flow may exist on a multilane highway if there are 2 mi or more between traffic signals. Where signals are more closely spaced, the facility should be analyzed as an urban street.

Many multilane highways will have periodic signalized intersections, even if the average signal spacing is well over 2 mi. In such cases, the multilane highway segments that are more than 2 mi away from any signalized intersections are analyzed by using the methodology of this chapter. Isolated signalized intersections should be analyzed with the methodology of Chapter 18, Signalized Intersections.

LOS procedures are provided for both automobiles and bicycles. The automobile methodology is based on the results of NCHRP Project 3-33 (*1*), and bicycle LOS is based on research conducted for the Florida Department of Transportation (*2*). The same methodology for bicycle LOS is used for both multilane and two-lane highways; readers interested in details of the bicycle methodology should refer to Chapter 15, Two-Lane Highways.

TYPES OF MULTILANE HIGHWAYS

Multilane highways generally have four to six lanes (in both directions) and posted speed limits between 40 and 55 mi/h. In some states, speed limits of 60 or 65 mi/h are used on some multilane highways. These highways may be divided by one of various median types, may be undivided (with only a centerline separating the directions of flow), or may have a two-way left-turn lane (TWLTL). They are typically located in suburban areas, leading into central cities, or along high-volume rural corridors, connecting two cities or two activity centers that generate a substantial number of daily trips. Exhibit 14-1 illustrates common types of multilane highways.

Traffic volumes on multilane highways vary widely but often have demand in the range of 15,000 to 40,000 veh/day. In some cases, volumes as high as 100,000 veh/day have been observed when access across the median is restricted and when major crossings are grade-separated. Bicycles are typically permitted on multilane highways, and multilane highways often serve as primary routes for both commuter cyclists (on suburban highways) and recreational cyclists (on rural highways).

BASE CONDITIONS

The base conditions under which the full capacity of a multilane highway segment is achieved include good weather, good visibility, no incidents or accidents, no work zone activity, and no pavement defects that would affect operations. This chapter's methodology assumes that these conditions exist. If any of these conditions do not exist, the speed, LOS, and capacity of the multilane highway segment can be expected to be worse than the predictions by this methodology.

Base conditions include good weather, good visibility, and no incidents or accidents. These conditions are always assumed to exist.

AR0073673

Exhibit 14-1
Multilane Highways

(a) Divided suburban multilane highway

(b) Undivided suburban multilane highway

(c) Suburban multilane highway with TWLTL

(d) Undivided rural multilane highway

Base conditions include 0% heavy vehicles and a driver population composed of regular users of the highway.

The methodology provides adjustments for situations in which these conditions do not apply.

Base conditions include the following conditions; the methodology can be adjusted to address situations in which these conditions do not exist:

- No heavy vehicles, such as trucks, buses, and recreational vehicles (RVs), in the traffic stream; and
- A driver population composed primarily of regular users who are familiar with the facility.

Characteristics such as lane width, total lateral clearance (TLC), median type, and access-point density will have an impact on the free-flow speed (FFS) of the facility. Curves describing operations under base conditions, however, account for differing FFSs.

FLOW CHARACTERISTICS UNDER BASE CONDITIONS

More severe geometric characteristics and the existence of access points are two key differences that result in lower multilane highway speeds and capacities than those of freeways with similar cross sections.

Uninterrupted flow on multilane highways is in most ways similar to that on basic freeway segments (Chapter 11). Several factors are different, however. Because side frictions are present in varying degrees from uncontrolled driveways and intersections as well as from opposing flows on undivided cross sections, speeds on multilane highways tend to be lower than those on similar basic freeway segments. The basic geometry of multilane highways also tends to be more severe than that of basic freeway segments because of the lower speed expectations. Last, isolated signalized intersections can exist along multilane highways. The overall result is that speeds and capacities on multilane highways are lower than those on basic freeway segments with similar cross sections.

AR0073674

Exhibit 14-2 shows speed–flow characteristics of multilane highway segments for various FFSs. Equations describing these curves are shown in Exhibit 14-3.

Curves are shown for FFSs between 45 mi/h and 60 mi/h. Because FFSs can vary widely, it is recommended that the FFS of a multilane highway segment be estimated to the nearest 5 mi/h, as follows:

42.5 mi/h ≤ FFS < 47.5 mi/h: use FFS = 45 mi/h,

47.5 mi/h ≤ FFS < 52.5 mi/h: use FFS = 50 mi/h,

52.5 mi/h ≤ FFS < 57.5 mi/h: use FFS = 55 mi/h,

57.5 mi/h ≤ FFS < 62.5 mi/h: use FFS = 60 mi/h

The FFS of a multilane highway segment should be estimated to the nearest 5 mi/h.

For multilane highway segments, speeds remain constant until they reach 1,400 pc/h/ln, after which speeds decline with further increases in flow rate.

Flow rates over 1,400 pc/h/ln result in speeds below the highway's FFS.

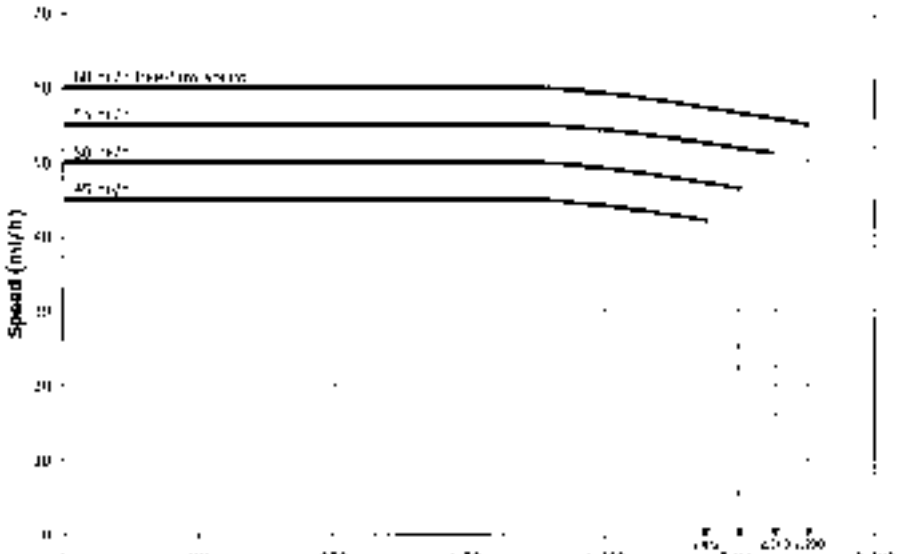

Exhibit 14-2
Speed–Flow Curves for Multilane Highways Under Base Conditions

Note: Max mum densities for LOS E occur at a flow rate of 1,400 pc/h/ln. These are 40, 41, 43, and 45 pc/mi/ln for FFSs of 60, 55, 50, and 45 mi/h, respectively.

FFS (mi/h)	For $v_p \leq 1{,}400$ pc/h/ln, S (mi/h)	For $v_p > 1{,}400$ pc/h/ln, S (mi/h)
60	60	$S = 60 - 1.76 \left[\frac{v_p - 1{,}400}{800} \right]^{2.7}$
55	55	$S = 55 - 3.76 \left[\frac{v_p - 1{,}400}{700} \right]^{2.7}$
50	50	$S = 50 - 3.48 \left[\frac{v_p - 1{,}400}{600} \right]^{2.7}$
45	45	$S = 45 - 2.76 \left[\frac{v_p - 1{,}400}{500} \right]^{2.7}$

Exhibit 14-3
Equations Describing Speed–Flow Curves in Exhibit 14-2

AR0073675

CAPACITY OF MULTILANE HIGHWAY SEGMENTS

Multilane highways with higher FFSs can also have higher base capacities. As these highways do not operate under base conditions, observed capacities will usually be lower than the base capacity.

The capacity of a multilane highway segment under base conditions varies with the FFS. For 60-mi/h FFS, the capacity is 2,200 pc/h/ln. For lesser FFSs, capacity diminishes. For 55-mi/h FFS, the capacity is 2,100 pc/h/ln, for 50-mi/h FFS, 2,000 pc/h/ln, and for 45-mi/h FFS, 1,900 pc/h/ln.

Capacities represent an average flow rate across all lanes. Individual lanes could have higher stable flows.

These values represent national norms. Capacity varies stochastically, and any given location could have a larger or smaller value. In addition, capacity refers to the average flow rate across all lanes. Thus, a two-lane (in one direction) multilane highway segment with a 60-mi/h FFS would have an expected capacity of 2 × 2,200 = 4,400 pc/h. This flow would not be uniformly distributed in the two lanes. Thus, one lane could have stable flows in excess of 2,200 pc/h/ln.

LOS FOR MULTILANE HIGHWAY SEGMENTS

Automobile Mode

Automobile LOS is defined by density.

Automobile LOS for multilane highway segments are defined in Exhibit 14-4. Because speeds are constant through a broad range of flow rates, LOS are defined on the basis of density, which is a measure of the proximity of vehicles to each other in the traffic stream.

Exhibit 14-4
Automobile LOS for Multilane Highway Segments

LOS	FFS (mi/h)	Density (pc/mi/ln)
A	All	≤11
B	All	>11–18
C	All	>18–26
D	All	>26–35
E	60	>35–40
	55	>35–41
	50	>35–43
	45	>35–45
F	Demand Exceeds Capacity	
	60	>40
	55	>41
	50	>43
	45	>45

LOS thresholds for multilane highways are the same as those for freeways for LOS A–D. However, multilane highway capacity (the LOS E–F boundary) occurs at lower densities.

For LOS A through D, the criteria are the same as those for basic freeway segments. This classification is appropriate, since both represent multilane uninterrupted flow. The boundary between LOS E and F, however, represents capacity. For multilane highways, capacity occurs at varying densities, depending on the FFS. The density at capacity ranges from 40 pc/mi/ln for 60-mi/h FFS to 45 pc/mi/ln for 45-mi/h FFS.

LOS F is determined when the demand flow rate exceeds capacity. When this occurs, the methodology does not produce a density estimate. Thus, although density in such cases will be above the thresholds shown, specific values cannot be determined.

Exhibit 14-5 shows LOS thresholds in relation to the base speed–flow curves.

AR0073676

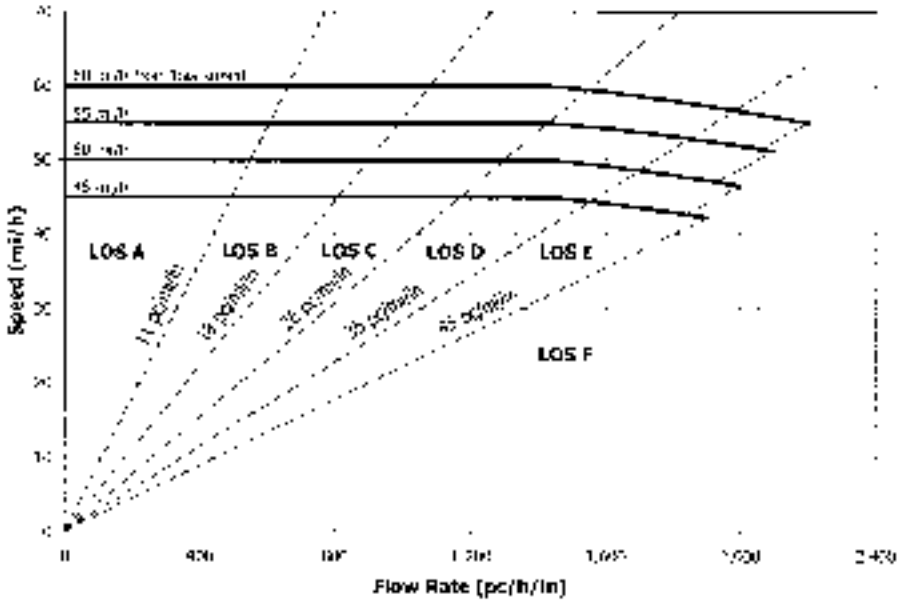

Exhibit 14-5
LOS for Base Speed Flow Curves

Automobile LOS Described

The descriptions of LOS for basic freeway segments given in Chapter 11 are also generally applicable to multilane highways. Vehicles entering the highway from a direct access point are an additional factor on multilane highways; these vehicles are not present on basic freeway segments and could result in a breakdown of flow at high flow rates.

The LOS thresholds for multilane highways reflect the collective professional judgment of the members of the Transportation Research Board's Highway Capacity and Quality of Service Committee. The upper values shown for LOS E (40 to 45 pc/mi/ln, depending on the FFS) represent the maximum density at which sustained flows at capacity are expected to occur. Breakdown (LOS F) conditions on multilane highways occur whenever the highway's demand exceeds its capacity.

Bicycle Mode

Bicycle LOS for multilane highway segments are based on a bicycle LOS score, which is in turn based on a traveler-perception index. Chapter 15, Two-Lane Highways, provides details about this index, which is identical for two-lane highways and multilane highways. The LOS ranges for bicycles on multilane highways are given in Exhibit 14-6.

Bicycle LOS is based on a traveler-perception index score. Details are given in Chapter 15.

LOS	Bicycle LOS Score
A	≤1.5
B	>1.5–2.5
C	>2.5–3.5
D	>3.5–4.5
E	>4.5–5.5
F	>5.5

Exhibit 14-6
Bicycle LOS on Multilane Highways

AR0073677

REQUIRED INPUT DATA

Automobile Mode

Analysis of a multilane highway segment requires details concerning the geometric characteristics of the segment and the demand characteristics of the users of the segment. This section presents the required input data for the basic freeway segment methodology; specifics about individual parameters are given in Section 2, Methodology.

Data Describing Multilane Highway Segment

The following information concerning the geometric features of the multilane highway segment is needed to conduct an analysis:

- FFS: 45 to 60 mi/h;
- Number of lanes (one direction): two or three;
- Lane width: 10 ft to more than 12 ft;
- Right-side lateral clearance: 0 ft to more than 6 ft;
- Median- (left-) side lateral clearance: 0 ft to more than 6 ft;
- Access point density: 0 to 40 points/mi;
- Terrain: level, rolling, or mountainous, or length and percent grade of specific grades; and
- Type of median: divided, TWLTL, or undivided.

Data Describing Demand

The following information is required concerning the users of the multilane highway segment:

- Demand during the analysis hour, or daily demand, *K* factor, and *D* factor;
- Heavy-vehicle presence (percent trucks and buses, percent RV's): 0%–100% in general terrain or 0%–25% for specific grades;
- Peak hour factor (PHF): up to 1.00; and
- Driver-population factor: 0.85–1.00.

Length of Analysis Period

The period for any multilane-highway analysis is generally the critical 15-min period within the peak hour. The methodology can be applied to any 15-min period, however.

If demand volumes are used, demand flow rates are estimated through the use of the PHF. When 15-min volumes are directly measured, the worst analysis period within the hour is selected, and flow rates are the 15-min volumes multiplied by 4. For subsequent computations in the methodology, the PHF is set to 1.00.

AR0073678

Bicycle Mode

The following data are required to evaluate bicycle LOS on a multilane highway; the ranges of values used in the development of the bicycle LOS model (3) are also shown:

- Width of the outside through lane: 10 to 16 ft,
- Shoulder width: 0 to 6 ft,
- Motorized vehicle volumes: up to 70,000 annual average daily traffic (AADT),
- Number of directional through lanes,
- Posted speed: 45 to 50 mi/h,
- Heavy-vehicle percentage: 0% to 2%, and
- Pavement condition: present serviceability rating of 1 to 5.

AR0073679

2. METHODOLOGY

This methodology is used to analyze the capacity, LOS, lane requirements, and impacts of traffic and design features on uninterrupted-flow segments of rural and suburban multilane highways.

LIMITATIONS OF METHODOLOGY

Automobile Mode

The methodology of this chapter does not take into account the following conditions:

- The negative impacts of poor weather conditions, traffic accidents or incidents, railroad crossings, or construction operations,
- Interference caused by parking on the shoulders of the multilane highway;
- The effect of lane drops and lane additions at the beginning or end of multilane highway segments,
- Possible queuing impacts when a multilane highway segment transitions to a two-lane highway segment,
- Differences between various types of median barriers and the difference between the impacts of a median barrier and a TWLTL;
- FFS below 45 mi/h or higher than 60 mi/h;
- Significant presence of on-street parking,
- Presence of bus stops that have significant use, and
- Significant pedestrian activity.

The last three factors are more representative of an urban or suburban arterial, but they may also exist on facilities with more than 2 mi between traffic signals. When the factors are present on uninterrupted-flow segments of multilane highways, the methodology does not deal with their impact on flow. In addition, this methodology cannot be applied to highways with a total of three lanes in both directions, which should be analyzed as two-lane highways with periodic passing lanes.

Uninterrupted-flow facilities that allow access solely through a system of on-ramps and off-ramps from grade separations or service roads should be analyzed as freeways.

Bicycle Mode

Although the bicycle LOS model has been successfully applied to rural multilane highways, users should be aware that conditions on many of these highways are outside the range of values used to develop the model.

The bicycle methodology was developed with data collected on urban and suburban streets, including facilities that would be defined as suburban multilane highways. Although the methodology has been successfully applied to rural multilane highways in different parts of the United States, users should be aware that conditions on many rural multilane highways (i.e., posted speeds of 55 mi/h or higher or heavy-vehicle percentages over 2%) will be outside the range of values used to develop the bicycle LOS model.

AR0073680

AUTOMOBILE MODE

Exhibit 14-7 provides an overview of this chapter's computational methodology for the automobile mode. It shows a typical operational analysis in which the LOS is determined for a specified set of geometric and traffic conditions. The methodology can also be used, as described in this chapter's Applications section, to determine the number of lanes needed to provide a target LOS, as well as to determine service flow rates, service volumes, and daily service volumes.

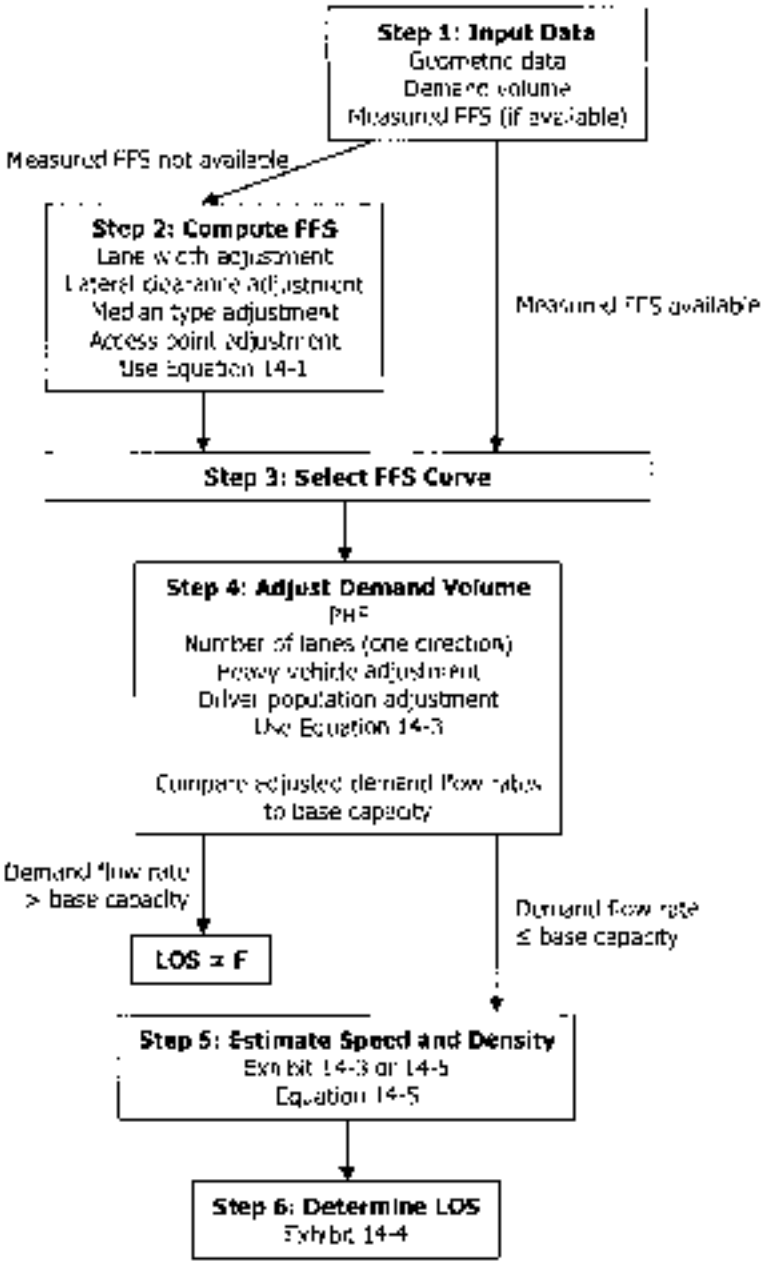

Exhibit 14-7
Overview of Multilane Highway Methodology for Automobile Mode

AR0073681

Step 1: Input Data

For a typical operational analysis, the analyst must specify (with either site-specific or default values) demand volume, number and width of lanes, right-side and median lateral clearance, type of median, roadside access points per mile, percent of heavy vehicles, such as trucks, buses, and RVs, PHF, terrain, and driver population factor.

Step 2: Compute FFS

FFS can be determined directly from field measurements or can be estimated as described below.

Field Measurement

FFS is the mean speed of passenger cars during periods of low to moderate flow

FFS is the mean speed of passenger cars measured during periods of low to moderate flow (up to 1,400 pc/h/ln). For a specific multilane highway segment, speeds are virtually constant in this range of flow rates. If the FFS can be field measured, this determination is preferable. If the FFS is measured directly, no adjustments are applied to the measured value.

The speed study should be conducted at a location representative of the segment at a time when flow rates are less than 1,400 pc/h/ln. The speed study should measure the speeds of all passenger cars or use a systematic sample (e.g., every tenth car in each lane). A sample of at least 100 passenger-car speeds should be obtained. Any speed measurement technique that has been found acceptable for other types of traffic engineering applications may be used. Further guidance on the conduct of speed studies is provided in a standard traffic engineering publication (3).

Estimation

It is not possible to make field measurements for future facilities, and field measurement may not be possible or practical for all existing ones. In such cases, the segment's FFS may be estimated by using Equation 14-1, which is based on the physical characteristics of the segment under study:

Equation 14-1

$$FFS = BFFS - f_{LW} - f_{LC} - f_M - f_A$$

where

- $BFFS$ = base FFS for multilane highway segment (mi/h),
- FFS = FFS of basic freeway segment (mi/h),
- f_{LW} = adjustment for lane width, from Exhibit 14-8 (mi/h),
- f_{LC} = adjustment for TLC, from Exhibit 14-9 (mi/h),
- f_M = adjustment for median type, from Exhibit 14-10 (mi/h), and
- f_A = adjustment for access-point density, from Exhibit 14-11 (mi/h).

AR0073682

Base FFS

This methodology covers multilane highway segments with FFS ranging from 45 mi/h to 60 mi/h. The most significant value in Equation 14-1 is the BFFS. There is not a great deal of information available to help establish a base value. In one sense, it is like the design speed—it represents the potential FFS based only on the horizontal and vertical alignment of the highway, not on the impacts of lane widths, lateral clearances, median type, or access points. The design speed may be used as the BFFS if it is available.

Although speed limits are not always uniformly set, the BFFS may be estimated, if necessary, as the posted or statutory speed limit plus 5 mi/h for speed limits 50 mi/h and higher and as the speed limit plus 7 mi/h for speed limits less than 50 mi/h.

Adjustment for Lane Width

Average lane widths less than 12 ft reduce the FFS.

The base condition for lane width is 12 ft or greater. When the average lane width across all lanes is less than 12 ft, the FFS is negatively affected. Adjustments to reflect the effect of narrow average lane widths are shown in Exhibit 14-8.

Exhibit 14-8
Adjustment to FFS for Average Lane Width

Lane Width (ft)	Reduction in FFS, f_{LW} (mi/h)
≥12	0.0
≥11–12	1.9
≥10–11	6.6

Adjustment for Lateral Clearance

Clearance restrictions on either the right or left side of the highway reduce the FFS.

The adjustment for lateral clearance on multilane highway segments is based on TLC at the roadside (right side) and at the median (left side). Fixed obstructions with lateral clearance effects include light standards, signs, trees, abutments, bridge rails, traffic barriers, and retaining walls. Standard raised curbs are not considered to be obstructions.

Right-side lateral clearance is measured from the right edge of the travel lanes to the nearest periodic or continuous roadside obstruction. If such obstructions are farther than 6 ft from the edge of the pavement, a value of 6 ft is used.

Left-side lateral clearance is measured from the left edge of the travel lanes to the nearest periodic or continuous obstruction in the median. If such obstructions are farther than 6 ft from the edge of the pavement, a value of 6 ft is used.

Use 6.0 as the left-side clearance for undivided highways and highways with TWTL.

Left-side lateral clearances are subject to some judgment. Many types of common median barriers do not affect driver behavior if they are no closer than 2 ft from the edge of the travel lane, including concrete and W-beam barriers. A value of 6 ft would be used in such cases. Also, when the multilane highway segment is undivided or has a TWTL, no left-side lateral clearance restriction is assumed, and a value of 6 ft is applied because there is a separate adjustment for the type of median that accounts for the impact of an undivided highway on FFS.

AR0073683

Equation 14-2 is used to determine TLC:

Equation 14-2

$$TLC = LC_R + LC_L$$

where

TLC = total lateral clearance (ft) (maximum value 12 ft),

LC_R = right-side lateral clearance (ft) (maximum value 6 ft), and

LC_L = left-side lateral clearance (ft) (maximum value 6 ft).

Exhibit 14-9 shows the reduction in FFS due to lateral obstructions on the multilane highway.

Exhibit 14-9
Adjustment to FFS for Lateral Clearance

Four-Lane Highways		Six-Lane Highways	
TLC (ft)	Reduction in FFS (mi/h)	TLC (ft)	Reduction in FFS (mi/h)
12	0.0	12	0.0
10	0.4	10	0.4
8	0.9	8	0.8
6	1.3	6	1.2
4	1.8	4	1.7
2	3.6	2	2.6
0	5.4	0	3.9

Note: Interpolation to the nearest 0.1 is recommended.

Adjustment for Type of Median

The FFS is reduced on undivided highways.

The adjustment for type of median is given in Exhibit 14-10. Undivided multilane highways reduce the BFFS by 1.6 mi/h.

Exhibit 14-10
Adjustment to FFS for Median Type

Median Type	Reduction in FFS, f_M (mi/h)
Undivided	1.6
TWTL	0.0
Divided	0.0

Adjustment for Access-Point Density

FFS is reduced as the access point density increases.

Exhibit 14-11 presents the adjustment to FFS for various levels of access-point density. Studies indicate that for each access point per mile, the estimated FFS decreases by approximately 0.25 mi/h, regardless of the type of median.

The number of access points per mile is determined by dividing the total number of access points (i.e., driveways and unsignalized intersections) on the right side of the highway in the direction of travel by the length of the segment in miles. An intersection or driveway should only be included in the count if it influences traffic flow. Access points that go unnoticed by drivers, or with little activity, should not be used to determine access-point density.

Exhibit 14-11
Adjustment to FFS for Access-Point Density

Access-Point Density (access points/mi)	Reduction in FFS, f_A (mi/h)
0	0.0
10	2.5
20	5.0
30	7.5
≥40	10.0

Note: Interpolation to the nearest 0.1 is recommended.

AR0073684

Although the calibration of this adjustment did not include one-way multilane highway segments, it might be appropriate to include intersection approaches and driveways on both sides of the facility in determining the access-point density on one-way segments.

Step 3: Select FFS Curve

As noted previously, once the multilane highway segment's FFS is determined, one of the four base speed–flow curves from Exhibit 14-2 is selected for use in the analysis. Interpolating between curves is not recommended. Criteria for selecting an appropriate curve were given in the text preceding Exhibit 14-2.

Step 4: Adjust Demand Volume

The basic speed–flow curves of Exhibit 14-2 are based on flow rates in equivalent passenger cars per hour, with the driver population dominated by regular users of the multilane highway segment. Demand volumes expressed as vehicles per hour under prevailing conditions must be converted to this basis. Equation 14-3 is used for this adjustment:

$$v_p = \frac{V}{PHF \times N \times f_{HV} \times f_p}$$

Equation 14-3

where

v_p = demand flow rate under equivalent base conditions (pc/h/ln);
V = demand volume under prevailing conditions (veh/h);
PHF = peak hour factor;
N = number of lanes (one direction);
f_{HV} = adjustment factor for presence of heavy vehicles in traffic stream, from Equation 14-4; and
f_p = adjustment factor for atypical driver populations.

PHF

The PHF represents the variation in traffic flows within an hour. Observations of traffic flow consistently indicate that the flow rates found in the peak 15 min within an hour are not sustained throughout the entire hour. The application of the PHF in Equation 14-3 accounts for this phenomenon.

On multilane highways, typical PHFs range from 0.75 to 0.95. Lower values are typical of lower volume conditions. Higher values are typical of urban and suburban peak hour conditions. Field data should be used if possible to develop PHFs that represent local conditions.

Adjustment for Heavy Vehicles

A *heavy vehicle* is defined as any vehicle with more than four wheels on the ground during normal operation. Such vehicles are generally categorized as trucks, buses, or RVs. Trucks cover a wide variety of vehicles, from single-unit trucks with dual-rear tires to triple-unit tractor–trailer combinations. Small

AR0073685

panel or pickup trucks with only four wheels are, however, classified as passenger cars. Buses include intercity buses, public transit buses, and school buses. Because buses are in many ways similar to single-unit trucks, both types of vehicles are considered in one category. RVs include a wide variety of vehicles from self-contained motor homes to cars and small trucks with trailers (for boats, all-terrain vehicles, or other items). The heavy vehicle adjustment factor f_{HV} is computed by using Equation 14-4:

Equation 14-4

$$f_{HV} = \frac{1}{1 + P_T(E_T - 1) + P_R(E_R - 1)}$$

where

f_{HV} = heavy-vehicle adjustment factor,

P_T = proportion of trucks and buses in traffic stream,

P_R = proportion of RVs in traffic stream,

E_T = passenger car equivalent (PCE) of one truck or bus in traffic stream, and

E_R = PCE of one RV in traffic stream.

The adjustment factor is found in a two-step process. First, the PCE for each truck, bus, and RV is found for the prevailing conditions under study. These equivalency values represent the number of passenger cars that would use the same amount of freeway capacity as one truck, bus, or RV under the prevailing conditions. Second, Equation 14-4 is used to convert the PCE values to the adjustment factor.

In many cases, trucks will be the only heavy vehicle present in the traffic stream. In others, the percentage of RVs will be small compared with trucks and buses. If the ratio of trucks and buses to RVs is 5:1 or greater, all heavy vehicles may be (but do not have to be) considered to be trucks.

The effect of heavy vehicles on traffic flow depends on terrain and grade conditions as well as traffic composition. PCEs can be selected for one of three conditions:

- Extended multilane highway segments in general terrain,
- Specific upgrades, or
- Specific downgrades.

Each of these conditions is more precisely defined and discussed below.

General terrain can be applied when:

Grades are <3%,

Grades are <5.2% for long, or

Grades are >3% and <5%, and are <0.50 mi long.

Equivalents for General Terrain Segments

General terrain refers to extended lengths of multilane highway containing a number of upgrades and downgrades where no single grade is long enough or steep enough to have a significant impact on the operation of the overall segment. As a guideline for this determination, extended segment analysis can be applied where no one grade of 3% or more is longer than 0.25 mi, or where no single grade between 2% and 3% is longer than 0.50 mi.

AR0073686

There are three categories of *general terrain*:

- *Level terrain*: Any combination of grades and horizontal or vertical alignment that permits heavy vehicles to maintain the same speed as passenger cars. This type of terrain typically contains short grades of no more than 2%.
- *Rolling terrain*: Any combination of grades and horizontal or vertical alignment that causes heavy vehicles to reduce their speed substantially below that of passenger cars but that does not cause heavy vehicles to operate at crawl speeds for any significant length of time or at frequent intervals. *Crawl speed* is the maximum sustained speed that trucks can maintain on an extended upgrade of a given percent. If the grade is long enough, trucks will be forced to decelerate to the crawl speed, which they can maintain for extended distances. Appendix A of Chapter 11, Basic Freeway Segments, contains truck performance curves that provide truck speeds for various lengths and severities of grade. The same curves may be used for uninterrupted-flow segments on multilane highways.
- *Mountainous terrain*: Any combination of grades and horizontal and vertical alignment that causes heavy vehicles to operate at crawl speed for significant distances or at frequent intervals.

Mountainous terrain is relatively rare. Generally, in segments severe enough to cause the type of operation described for mountainous terrain, there will be individual grades that are longer and steeper than the criteria for general terrain analysis.

The mountainous terrain category is rarely used, because individual grades will typically be longer and steeper than the criteria for general terrain analysis.

Exhibit 14-12 shows PCEs for trucks and buses and RVs in general terrain segments.

Exhibit 14-12
PCEs for Heavy Vehicles in General Terrain Segments

Vehicle	PCE by Type of Terrain		
	Level	Rolling	Mountainous
Trucks and buses, E_T	1.5	2.5	4.5
RVs, E_R	1.2	2.0	4.0

Equivalents for Specific Upgrades

Any grade between 2% and 3% and longer than 0.5 mi, or 3% or greater and longer than 0.25 mi, should be considered to be a separate segment. The analysis of such segments must consider the upgrade conditions and the downgrade conditions separately, as well as whether the grade is a single, isolated grade of constant percentage or part of a series forming a composite grade. Appendix A of Chapter 11 discusses the analysis of composite grades.

Exhibit 14-13 and Exhibit 14-14 give values of I_D and I_R for trucks and buses and for RVs, respectively. These factors vary with the percent of grade, length of grade, and the proportion of heavy vehicles in the traffic stream. Maximum values occur when there are only a few heavy vehicles in the traffic stream. The equivalents decrease as the number of heavy vehicles increases because these vehicles tend to form platoons. Because heavy vehicles have more uniform operating characteristics, fewer large gaps are created in the traffic stream when they platoon, and the impact of a single heavy vehicle in a platoon is less severe than that of a single heavy vehicle in a stream primarily composed of passenger

AR0073687

cars. The aggregate impact of heavy vehicles on the traffic stream, however, increases as the number and percentage of heavy vehicles increase.

Exhibit 14-13
PCEs for Trucks and Buses (E_T) on Upgrades

Percent Upgrade	Length (mi)	Proportion of Trucks and Buses 2%	4%	5%	6%	8%	10%	15%	20%	25%
≤2	All	1.5	1.5	1.5	1.5	1.5	1.5	1.5	1.5	1.5
>2 – 3	0.00 – 0.25	1.5	1.5	1.5	1.5	1.5	1.5	1.5	1.5	1.5
	>0.25 – 0.50	1.5	1.5	1.5	1.5	1.5	1.5	1.5	1.5	1.5
	>0.50 – 0.75	1.5	1.5	1.5	1.5	1.5	1.5	1.5	1.5	1.5
	>0.75 – 1.00	2.0	2.0	2.0	2.0	1.5	1.5	1.5	1.5	1.5
	>1.00 – 1.50	2.5	2.5	2.5	2.5	2.0	2.0	2.0	2.0	2.0
	>1.50	3.0	3.0	3.0	3.0	2.0	2.0	2.0	2.0	2.0
>3 – 4	0.00 – 0.25	1.5	1.5	1.5	1.5	1.5	1.5	1.5	1.5	1.5
	>0.25 – 0.50	2.0	2.0	2.0	2.0	2.0	2.0	1.5	1.5	1.5

	>0.50 – 0.75	4.5	4.0	4.0	4.0	2.5	2.5	2.5	2.5	2.5
	>0.75 – 1.00	4.0	3.5	3.5	3.5	3.0	3.0	3.0	3.0	3.0
	>1.00	5.0	4.0	4.0	4.0	3.5	3.5	3.0	3.0	3.0
>5 – 6	0.00 – 0.25	2.0	2.0	1.5	1.5	1.5	1.5	1.5	1.5	1.5
	>0.25 – 0.50	4.0	3.0	2.5	2.5	2.0	2.0	2.0	2.0	2.0
	>0.50 – 0.75	5.0	4.5	4.0	3.5	3.0	3.0	3.0	3.0	3.0
	>0.75 – 1.00	5.5	5.0	4.5	4.0	3.0	3.0	3.0	4.0	3.0
	>1.00	6.0	5.0	5.0	4.5	3.5	3.5	3.5	4.5	4.5
>6	0.00 – 0.25	4.0	3.0	2.5	2.5	2.5	2.5	2.0	2.0	1.0
	>0.25 – 0.50	4.5	4.0	3.5	3.5	3.5	3.0	2.5	2.5	2.5
	>0.50 – 0.75	5.0	4.5	4.0	4.0	3.5	3.0	2.5	2.5	2.5
	>0.75 – 1.00	5.5	5.0	4.5	4.5	4.0	3.5	3.0	3.0	3.0
	>1.00	6.0	5.5	5.0	5.0	4.5	4.0	3.5	4.5	3.5
	>1.00	7.0	6.0	5.5	5.5	5.0	4.5	4.0	4.0	4.0

Note: Interpolation for percentages of trucks and buses is recommended to the nearest 0.5.

Exhibit 14-14
PCEs for RVs (E_R) on Upgrades

Percent Upgrade	Length (mi)	Proportion of RVs 2%	4%	5%	6%	8%	10%	15%	20%	25%
≤2	All	1.2	1.2	1.2	1.2	1.2	1.2	1.2	1.2	1.2
>2 – 3	0.00 – 0.50	1.2	1.2	1.2	1.2	1.2	1.2	1.2	1.2	1.2
	>0.50	3.0	1.5	1.5	1.5	1.5	1.5	1.2	1.2	1.2
>3 – 4	0.00 – 0.25	1.2	1.2	1.2	1.2	1.2	1.2	1.2	1.2	1.2
	>0.25 – 0.50	2.5	2.5	2.0	2.0	2.0	2.0	1.5	1.5	1.5
	>0.50	3.0	2.5	2.5	2.5	2.0	2.0	2.0	1.5	1.5
>4 – 5	0.00 – 0.25	2.5	2.0	2.0	2.0	1.5	1.5	1.5	1.5	1.5
	>0.25 – 0.50	4.0	3.0	3.0	3.0	2.5	2.5	2.0	2.0	2.0
	>0.50	4.5	3.5	3.0	3.0	3.0	2.5	2.5	2.0	2.0
>5	0.00 – 0.25	4.0	3.0	2.5	2.5	2.5	2.0	2.0	2.0	1.5
	>0.25 – 0.50	5.0	4.0	4.0	4.0	3.5	3.0	3.0	2.5	2.0
	>0.50	6.0	4.5	4.0	4.0	3.5	3.0	3.0	2.5	2.0

Note: Interpolation for percentages of RVs is recommended to the nearest 0.1.

The grade length should include 25% of the length of the vertical curves at the start and end of the grade.

With two consecutive upgrades, 50% of the length of the vertical curve joining them should be included.

The length of the grade is generally taken from a highway profile. It typically includes the straight portion of the grade plus some portion of the vertical curves at the beginning and end of the grade. It is recommended that 25% of the length of the vertical curves at both ends of the grade be included in the length. Where two consecutive upgrades are present, 50% of the length of the vertical curve joining them is included in the length of each grade.

AR0073688

In the analysis of upgrades, the point of interest is generally at the end of the grade, where heavy vehicles have the maximum effect on operations. However, if a segment ends midgrade (because of a major access point, for example), the length of the grade to the end of the segment would be used.

The point of interest in the analysis of upgrades is usually the spot where heavy vehicles would have the greatest impact on operations (for example, the top of a grade or the top of the steepest grade in a series).

On composite grades, the relative steepness of segments is important. If a 5% upgrade is followed by a 2% upgrade, for example, the maximum impact of heavy vehicles is most likely at the end of the 5% segment. Heavy vehicles would be expected to accelerate after entering the 2% segment.

Equivalents for Specific Downgrades

Knowledge of specific impacts of heavy vehicles on operating conditions on downgrades is limited. In general, if the downgrade is not severe enough to cause trucks to shift into a lower gear (to engage engine braking), heavy vehicles may be treated as if they were on level terrain segments. Where a downgrade is severe, trucks must often use low gears to avoid gaining too much speed and running out of control. In such cases, their effect on operating conditions is more significant than on level terrain. Exhibit 14-15 gives values of E_T for this situation.

Exhibit 14-15
PCEs for Trucks and Buses (E_T) on Specific Downgrades

Percent Downgrade	Length of Grade (mi)	Proportion of Trucks and Buses			
		5%	10%	15%	20%
≤4	All	1.5	1.5	1.5	1.5
>4 – 5	≤4	1.5	1.5	1.5	1.5
	>4	2.0	2.0	2.0	1.5
>5 – 6	≤4	1.5	1.5	1.5	1.5
	>4	5.5	4.0	4.0	3.0
>6	≤4	1.5	1.5	1.5	1.5
	>4	7.5	6.0	5.5	4.5

On downgrades, RVs are always treated as if they were on level terrain. E_R is therefore always 1.2 on downgrades regardless of the length or severity of the downgrade or the percentage of RVs in the traffic stream.

E_R is always 1.2 on downgrades.

Equivalents for Composite Grades

The vertical alignment of most multilane highways results in a continuous series of grades. It is often necessary to determine the effect of a series of grades in succession. The most straightforward technique is to compute the *average grade*, defined as the total rise from the beginning of the composite grade to the point of interest divided by the length of the grade (to the point of interest).

The average grade can be used when all component grades are <4% or the total length of the grade is <4,000 ft.

The average grade technique is an acceptable approach for grades in which all subsections are less than 4% or the total length of the grade is less than 4,000 ft. For more severe composite grades, a detailed technique is presented in Appendix A of Chapter 11, Basic Freeway Segments. This technique uses vehicle performance curves and equivalent speeds to determine the equivalent simple grade for analysis. It can be applied to composite grades on multilane highways.

Appendix A of Chapter 11 provides a method for addressing more severe composite grades.

Adjustment for Driver Population

The base traffic stream characteristics for multilane highway segments are representative of regular drivers in a traffic stream composed substantially of commuters, or drivers who are familiar with the facility. It is generally accepted

AR0073689

that traffic streams composed of driver populations with different characteristics (e.g., recreational drivers) use freeways less efficiently. Although data are sparse and reported results vary substantially, significantly lower capacities have been reported on weekends, particularly in recreational areas. It may generally be assumed that the reduced capacity (1,650 pc/h/ln) extends to service flow rates and service volumes for other LOS as well.

A default value of 1.00 should generally be used, reflective of drivers who are typically users of the facility.

The adjustment factor f_p is used to reflect the effect of driver population. The values of f_p usually range from 0.85 to 1.00, although lower values have been observed in some cases. In general, the analyst should use a value of 1.00, which reflects commuters or otherwise familiar drivers, unless there is sufficient evidence that a lower value should be used. Where greater accuracy is needed, comparative field studies of commuter and recreational traffic flow and speeds are recommended.

Does LOS F Exist?

At this point, the demand flow rate has been computed and is stated in units of passenger cars per hour per lane under equivalent base conditions. This demand flow rate must be compared with the base capacity (in the same units). If demand exceeds capacity, LOS F is assigned, and the analysis ends. If demand is less than capacity, LOS F does not exist, and the analysis continues.

Step 5: Estimate Speed and Density

At this point in the methodology, the following have been determined: (a) the FFS and appropriate SFF curve for use in the analysis, and (b) the demand flow rate expressed in passenger cars per hour per lane under equivalent base conditions. With this information, the estimated speed and density of the traffic stream may be determined.

With the equations specified in Exhibit 14-3, the expected mean speed of the traffic stream can be computed. A graphical solution using Exhibit 14-2 can also be performed.

With the estimated speed determined, Equation 14-5 is used to estimate the density of the traffic stream.

Equation 14-5

$$D = \frac{v_p}{S}$$

where

D = density (pc/mi/ln),
v_p = demand flow rate (pc/h/ln), and
S = mean speed of traffic stream (mi/h).

Step 6: Determine LOS

Exhibit 14-4 is entered with the density obtained from Equation 14-5 to determine the expected prevailing LOS.

AR0073690

BICYCLE MODE

The calculation of bicycle LOS on multilane and two-lane highways shares the same methodology, since multilane and two-lane highways operate in fundamentally the same manner for bicyclists and car drivers. Cyclists travel much more slowly than the prevailing traffic flow and stay as far to the right as possible, including using paved shoulders when available. This similarity indicates the need for only one model.

For bicycle LOS mode, for multilane highways uses a traveler perception index calibrated by using a linear regression model. The model fits independent variables associated with roadway characteristics to the results of a user survey that rates the comfort of various bicycle facilities. The resulting bicycle LOS index computes a numerical LOS score, generally ranging from 0.5 to 6.5, which is stratified to produce a LOS A to F result by using Exhibit 14-6.

Full details on the bicycle LOS methodology and calculation procedures are given in Chapter 15, Two-Lane Highways.

Follow the step-by-step description of the bicycle LOS method given in Chapter 15, Two-Lane Highways, when service LOS on multilane highways is calculated.

AR0073691

3. APPLICATIONS

The analysis methodology for multilane highway segments is relatively straightforward. Thus, it can be directly used in any one of four applications:

1. *Operational analysis*. All traffic and roadway conditions are specified for an existing facility or a future facility with forecast conditions. The existing or expected LOS is determined.
2. *Design analysis*. A forecast demand volume is used, and key design parameters are specified (e.g., lane width and lateral clearance). The number of lanes required to deliver a target LOS is determined.
3. *Planning and preliminary engineering*. The basic scenario is the same as that for design analysis except that the analysis is conducted at a much earlier stage in the development process. Inputs include default values, and the demand volume is usually stated as an AADT.
4. *Service flow rate and service volume*. The service flow rate, service volume, daily service volume, or all three are estimated for each LOS for an existing or future facility. All traffic and roadway conditions must be specified for this type of analysis.

Because the methodology and its algorithms are simple and do not involve iterations, all of the types of analysis cited can be completed without the iterative approach required by many other HCM methodologies.

DEFAULT VALUES

For this chapter's methodology, a range of input data is needed. Most of these data should be field measured or estimated values for the specific segment under consideration. When some of the data are not available, default values may be used. However, use of default values will affect the accuracy of the output. Exhibit 14-16 shows the data that are required to conduct an operational analysis and the recommended default values when site-specific data are unavailable (1).

Exhibit 14-16
Required Input Data and Default Values for Multilane Highway Segments

Required Data	Default Values
Geometric Data	
Number of lanes in one direction	2 or 3 (in one direction); must have site-specific value
Lane width	12 ft
TLC	12 ft
Access-point density	8 access points/mi (rural) 16 access points/mi (low-density suburban) 25 access points/mi (high-density suburban)
Length of specific grade (%, length)	No default; must have site-specific value
Base FFS	65 mi/h [illegible]
Demand Data	
Length of analysis period	15 min
PHF	0.88, rural; 0.95, suburban
Percentage of heavy vehicles	10%, rural; 5%, urban*
Driver population factor	1.00

Note: *Refer to site-specific default values for percentage of heavy vehicles as given in Chapter 26, Freeway and Highway Segments: Supplemental.

AR0073692

The analyst may also replace the default values in Exhibit 14-16 with defaults that have been locally calibrated.

ESTABLISHING ANALYSIS BOUNDARIES

The methodology of this chapter applies to an uninterrupted flow segment of multilane highway with uniform prevailing conditions. Thus, any point at which one or more of the prevailing conditions change should mark the beginning of a new analysis segment. The following conditions generally necessitate segmenting the highway:

- A change in the basic number of travel lanes on the highway;
- A change in the highway's median treatment;
- A change of grade of 2% or more on a constant upgrade longer than 1,000 ft;
- The presence of a traffic signal, stop sign, or roundabout along the multilane highway;
- A significant change in the cross-point density;
- A change in the speed limit;
- An access point at which a significant number or percentage of vehicles enters or leaves the highway; and
- The presence of a bottleneck condition.

Locate changes of 2% or more, changes in the highway's geometric characteristics, changes in speed limit, signalized intersections of the highway, and major access points are places where multilane highways should be segmented.

In general, when analysis boundaries are established, the minimum length of a study segment should be 2,500 ft. The boundary of a study segment should be no closer than 0.25 mi to a traffic signal.

TYPES OF ANALYSIS

Operational Analysis

The operational analysis application was fully specified in the Methodology section of this chapter. Operational analysis begins with all input parameters specified and is used to find the expected LOS that would result from the prevailing roadway and traffic conditions.

Operational analysis finds the expected LOS for specified roadway and traffic conditions.

Design Analysis

In design analysis, a known demand volume is used to determine the number of lanes needed to deliver a target LOS. Two modifications are required to the operational analysis methodology. First, since the number of lanes is to be determined, the demand volume is converted to a demand flow rate in passenger cars per hour, not passenger cars per hour per lane, by using Equation 14-6 instead of Equation 14-3.

Design analysis finds the number of lanes required for a target LOS given a specified demand volume.

$$v = \frac{V}{PHF \times f_{HV} \times f_p} \qquad \text{Equation 14-6}$$

where v is the demand flow rate in passenger cars per hour and all other variables are as previously defined.

AR0073693

Second, a maximum service flow rate for the target LOS is then selected from Exhibit 14-17. These values are selected from the base speed–flow curves of Exhibit 14-5 for each LOS.

Exhibit 14-17
Maximum Service Flow Rates (pc/h/ln) for Multilane Highway Segments Under Base Conditions

FFS (mi/h)	Target LOS				
	A	B	C	D	E
60	660	1,080	1,550	1,980	2,200
55	600	990	1,420	1,810	2,100
50	550	900	1,300	1,710	2,000
45	290	810	1,170	1,550	1,900

Then the number of lanes required to deliver the target LOS can be found from Equation 14-7:

Equation 14-7

$$N = \frac{v}{MSF_i}$$

where N is the number of lanes required and MSF_i is the maximum service flow rate for LOS i from Exhibit 14-17. Equation 14-6 and Equation 14-7 can be conveniently combined as Equation 14-8:

Equation 14-8

$$N = \frac{V}{MSF_i \times PHF \times f_{HV} \times f_p}$$

where all variables are as previously defined.

All fractional values of N must be rounded up.

The value of N resulting from Equation 14-7 or Equation 14-8 will most likely be fractional. Because only integer numbers of lanes can be constructed, the result is always rounded to the next higher value. Thus, if the result is 2.1 lanes, 3 lanes must be provided. In effect, the minimum number of lanes needed to provide the target LOS is 2.1. If the result were rounded to 2, a poorer LOS than the target value would result.

Because only whole lanes can be built, it may not be possible to achieve the target LOS for a given demand volume.

This rounding-up process will occasionally produce an interesting result: it is possible that a target LOS (for example, LOS C) cannot be achieved for a given demand volume. If 2 lanes are required to produce LOS C, providing two lanes would drop the LOS, most likely to D. However, if three lanes are provided, the LOS might actually improve to B. Thus, some judgment may be required to interpret the results. In this case, two lanes might be provided even though they would result in a borderline LOS D. Economic considerations might lead a decision maker to accept a slightly lower operating condition than that originally targeted.

Planning and Preliminary Engineering

Planning and preliminary engineering applications also find the number of lanes required to deliver a target LOS but require more generalized input values to the methodology.

The objective of planning or preliminary engineering is to get a general idea of the number of lanes that will be required to deliver a target LOS. The primary differences are that many default values will be used, and the demand volume will be usually expressed as an AADT. Thus, a planning and preliminary engineering analysis starts by converting the demand expressed as an AADT to an estimate of the directional peak-hour demand volume (DDHV), as shown in Equation 14-9:

AR0073694

$$V = DDHV = AADT \times K \times D$$

Equation 14-9

where K is the proportion of AADT occurring during the peak hour, D is the proportion of peak-hour volume traveling in the peak direction, and all other variables are as previously defined.

Chapter 2, Modal Characteristics, provides additional guidance on K- and D-factors.

Once the hourly demand volume is estimated, the methodology follows the same path as that for design analysis.

Service Flow Rates, Service Volumes, and Daily Service Volumes

This chapter's methodology can be easily manipulated to produce service flow rates, service volumes, or daily service volumes, or all three, for a multilane highway segment.

Exhibit 14-17 gives values of the maximum service flow rates MSF_i for each LOS for multilane highways of various FFSs. These values are given in terms of passenger cars per hour per lane under equivalent base conditions. A service flow rate SF_i is the maximum rate of flow that can exist while LOS i is maintained during the 15-min analysis period under prevailing conditions. It can be computed from the maximum service flow rate by using Equation 14-10:

$$SF_i = MSF_i \times N \times f_{HV} \times f_p$$

Equation 14-10

where all variables are as previously defined.

A service flow rate can be converted to a service volume SV_i by applying a PHF, as shown in Equation 14-11. A service volume is the maximum hourly volume that can exist while LOS i is maintained during the worst 15-min period of the analysis hour.

$$SV_i = SF_i \times PHF$$

Equation 14-11

where all variables are as previously defined.

A daily service volume DSV_i is the maximum AADT that can be accommodated by the facility under prevailing conditions while LOS i is maintained during the worst 15-min period of the analysis day. It is estimated from Equation 14-12:

$$MSV_i = \frac{SV_i}{K \times D}$$

Equation 14-12

where all variables are as previously defined.

GENERALIZED DAILY SERVICE VOLUMES

Exhibit 14-18 and Exhibit 14-19 are generalized daily service volume tables for multilane highway segments or facilities. They are based on a set of specified typical conditions for rural and urban multilane highways:

- Percent HV = 10% (rural), 5% (urban),
- FFS = 60 mi/h,
- PHF = 0.88 (rural), 0.95 (urban); and
- Driver population factor $f_p = 1.00$.

AR0073695

Values of rural and urban daily service volumes are provided for four-lane and six-lane highways in level and rolling terrain. A range of K and D factors is provided. Users should enter Exhibit 14-18 and Exhibit 14-19 with local or regional values of these factors for the appropriate size of multilane highway in the appropriate terrain.

	0.60	27.2	39.0	49.8	55.4	40.8	64.4	74.7	83.0
	0.65	25.1	36.0	46.0	51.1	37.6	59.4	69.0	76.6

Note: Key assumptions: 8% trucks, 5% RVs, 67 mi/h FFS, drive population factor 1.0

Exhibit 14-18 and Exhibit 14-19 must be used with care. Because the characteristics of any given multilane highway may or may not be typical, the values should not be used in the analysis of a specific segment of multilane highway. The exhibits are intended to allow a general evaluation of many facilities within a given jurisdiction on a first-pass basis to identify those segments or facilities that might be in need of remediation. Any segments or facilities so identified should then be submitted to specific analysis by using this chapter's methodology and each segment's site-specific characteristics. Exhibit 14-18 and Exhibit 14-19 should not be used to make final decisions on which segments or facilities to upgrade or on the specific designs proposed for such upgrades.

Daily service volumes are computed with Equation 14-10 through Equation 14-12, which combined yield Equation 14-13:

$$DSV_{i,j} = \frac{MSF_i \times N \times f_{HV,i} \times f_{p,i} \times PHF}{K \times D} \quad \text{Equation 14-13}$$

AR0073697

where all variables are as previously defined. Values of MSF are selected from Exhibit 24-18 or Exhibit 24-19 for the typical FFS of 60 mi/h. Exhibit 24-18 and Exhibit 24-19 do not show LOS A, since this level is rarely of interest in assessing improvement programs.

For multilane highways, daily service volume tables are quite easy to construct by using localized typical values and local defaults. Equation 24-13 is easily applied. All of the variables in the equation simply have to be defined for a given FFS. The heavy-vehicle adjustment depends on PCEs, which are easily obtained for each of the terrain categories.

USE OF ALTERNATIVE TOOLS

Except for the effects of interaction with other facilities, the limitations of the methodology that were stated earlier in the chapter have minimal potential to be addressed by alternative tools. There is thus insufficient experience with alternative tools to support the development of useful guidance for their application to multilane highways.

AR0073698

4. EXAMPLE PROBLEMS

Exhibit 14-20
List of Example Problems

Problem Number	Description	Application
1	LOS on an undivided four-lane highway	Operational analysis
2	LOS on a five-lane highway with TWLTL	Operational analysis
3	Design cross-section required to provide target LOS	Design analysis
4	Multilane highway modernization	Planning analysis
5	Four-lane cross section required to provide target LOS	Planning analysis

EXAMPLE PROBLEM 1: LOS ON UNDIVIDED FOUR-LANE HIGHWAY

A 3.25-mi, undivided four-lane highway is primarily on level terrain. The highway does, however, contain one sustained grade of 2.5% that is 0,200 ft long. At what LOS is the highway expected to operate?

The Facts

- Level terrain; 0.200 ft, 2.5% grade in Cadiol;
- Base FFS = 65 mi/h;
- Lane width, 11 ft;
- Clearance at roadside 4 ft;
- Access points per mile: 20;
- Peak-hour volume: 1,900 veh/h;
- Traffic composition: 10% trucks, 2% RVs;
- PHF = 0.90, and
- Familiar facility users

Comments

Three solutions will be needed in this case: (a) for the level terrain portion of the highway, (b) for the 2.5% upgrade portion of the highway, and (c) for the 2.5% downgrade portion of the highway. The factor that will vary for each of these is the heavy-vehicle adjustment factor.

Step 1: Input Data

All input data are specified in the example problem statement.

Step 2: Compute FFS

The FFS is estimated with Equation 14-1. The BFFS is given as 65 mi/h. Adjustments are needed for

- Lane width (f_{LW} = 1.9 mi/h (Exhibit 14-8, with 11-ft lanes),
- Lateral clearance (f_{LC} = 0.4 mi/h (Exhibit 14-9, with TLC = 4 + 6 = 10 ft, four lanes),
- Median type (f_M = 1.6 mi/h (Exhibit 14-10, for undivided highways), and
- Access-point density (f_A = 5.0 mi/h (Exhibit 14-11, with 20 access points/mi).

AR0073699

Then

$$FFS = BFFS - f_{LW} - f_{LC} - f_{M} - f_{A}$$

$$FFS = 65.0 - 1.9 - 0.4 - 1.6 - 5.0 = 56.1 \text{ mi/h}$$

Step 3: Select FFS Curve

FFSs are all rounded to the nearest 5 mi/h. Therefore, the FFS used in the calculations will be 55 mi/h.

Step 4: Adjust Demand Volume

The demand volume, stated in vehicles per hour under prevailing conditions, must be converted to a demand flow rate in passenger cars per hour under base conditions by using Equation 14-3:

$$v_p = \frac{V}{PHF \times N \times f_{HV} \times f_p}$$

where

V = demand volume (veh/h) (3,900 veh/h, given),

PHF = peak hour factor (0.90, given), and

f_p = driver population factor (1.00, familiar users).

The heavy vehicle adjustment factor is computed by using Equation 14-4:

$$f_{HV} = \frac{1}{1 + P_T (E_T - 1) + P_R (E_R - 1)}$$

Three sets of PCEs have to be determined: for level terrain, for 2.5% upgrade, and for 2.5% downgrade.

- Level terrain: $E_T = 1.5$ (Exhibit 14-12); $E_R = 1.2$ (Exhibit 14-12);
- Upgrade $E_T = 1.5$ (Exhibit 14-13, with 13% trucks and a 2.5% grade: 3,200/5,280 = 0.61 mi); $E_R = 3.0$ (Exhibit 14-14 with 2% RVs and 2.5% grade for 0.61 mi); and
- Downgrade $E_T = 1.5$ (Exhibit 14-15 with less than 4% grade and 13% trucks); $E_R = 1.2$ (from the text following Exhibit 14-15)

In this case, the equivalents are the same for the level terrain segments and the 2.5% downgrade. Consequently, there are only two different heavy vehicle adjustment factors to work with.

$$f_{HV}(\text{level, down}) = \frac{1}{1 + 0.13(1.5 - 1) + 0.02(1.2 - 1)} = 0.935$$

$$f_{HV}(\text{up}) = \frac{1}{1 + 0.13(1.5 - 1) + 0.02(3.0 - 1)} = 0.905$$

AR0073700

There are thus two values of flow rate in passenger cars per hour under base conditions.

$$v_p(\text{level, down}) = \frac{1{,}900}{0.90 \times 2 \times (0.905 \times 1)} = 1{,}129 \text{ pc/h}$$

$$v_p(\text{up}) = \frac{1{,}900}{0.90 \times 2 \times (0.905 \times 1)} = 1{,}166 \text{ pc/h}$$

Step 5: Estimate Speed and Density

Speed for the two demand levels can be estimated by using the equations in Exhibit 14-3 or graphically by using Exhibit 14-3. In this case, both demand flow rates, 1,129 pc/h and 1,166 pc/h, are less than 1,400 pc/h. From Exhibit 14-3, the speed for both of these situations is the FFS, or 55 mi/h.

The densities of the general-terrain and specific-grade segments are then computed with Equation 14-5:

$$D = \frac{v_p}{S}$$

$$D(\text{level, down}) = \frac{1{,}129}{55} = 20.5 \text{ pc/mi/ln}$$

$$D(\text{up}) = \frac{1{,}166}{55} = 21.2 \text{ pc/mi/ln}$$

Step 6: Determine LOS

As shown in Exhibit 14-4, the LOS for both densities is C.

Discussion

The multilane highway described here operates at LOS C throughout the entire study area, including the upgrade and the downgrade within it. In a sense, this problem involves a *facility* as opposed to a *segment*. The facility contains several component segments: level terrain segments on either side of the 2.3%, 3,200-ft grade and the uphill and downhill portions of the 2.3% grade itself.

This chapter's methodology applies to uniform multilane highway segments. In this example problem, there were three segments, which together formed a facility of more than 3 mi. LOS C on all segments is very likely acceptable and would not generally call for immediate remediation.

EXAMPLE PROBLEM 2: LOS ON FIVE-LANE HIGHWAY WITH TWLTL

An 11,000-ft segment of a five-lane highway (two travel lanes in each direction plus a TWLTL) includes a 4% grade of 6,000 ft followed by 5,000 ft of level terrain. At what LOS is the facility expected to operate?

The Facts

- Lane width: 12 ft;
- External clearance, both sides of the roadway: 12 ft;

AR0073701

- Traffic composition: 6% trucks, 0% RVs;
- Access points per mile on the level segment: eastbound, 10; westbound, 13;
- Access points per mile on the specific grade segment: eastbound, 19; westbound, 0;
- PHF = 0.90;
- Familiar users of the facility;
- Peak-hour demand, 1,300 veh/h;
- The upgrade occurs in the westbound direction; and
- Posted speed limit = 45 mi/h.

Comments

This problem is similar to Example Problem 1 in that there are three segments in the facility as described, each of which must be analyzed. The upgrade and downgrade on the 4% grade must be separately analyzed, as well as the level terrain segment. This case is a bit more complex, since not all characteristics of the segments are the same, particularly access points. Because no BFFS is given, it will be estimated as the speed limit plus 7 mi/h, or 45 + 7 = 52 mi/h.

Step 1: Input Data

All input data are given in the example problem statement.

Step 2: Compute FFS

The FFS is estimated by using Equation 14-1:

$$FFS = BFFS - f_{LW} - f_{LC} - f_M - f_A$$

In this case, the BFFS is estimated to be 52 mi/h. The lane width is 12 ft, which is the base condition; therefore f_{LW} = 0.0 mi/h (Exhibit 14-8). The lateral clearance is 12 ft at each roadside, but a maximum value of 6 ft may be used. A TWLTL is considered to have a median lateral clearance of 6 ft. Thus, the TLC is 6 + 6 = 12 ft, which is also a base condition. Therefore, f_{LC} = 0.0 mi/h (Exhibit 14-9). The median type adjustment f_M is also 0.0 mi/h (Exhibit 14-10).

For this example problem, only the access point density produces a nonzero adjustment to the BFFS. Both eastbound (EB) segments (level terrain, 4% downgrade) have 10 access points/mi. From Exhibit 14-11, the corresponding adjustment factor is 2.5 mi/h. The westbound (WB) level terrain segment has 13 access points/mi, and an adjustment factor of 3.3 mi/h (by interpolation in Exhibit 14-11). The WB upgrade has 0 access points/mi and an adjustment factor of 0.0 mi/h. Therefore:

$$FFS_{(EB\ level,\ composite)} = 52.0 - 0.0 - 0.0 - 0.0 - 2.5 = 49.5\ \text{mi/h}$$

$$FFS_{(WB\ level)} = 52.0 - 0.0 - 0.0 - 0.0 - 3.3 = 48.7\ \text{mi/h}$$

$$FFS_{(WB\ upgrade)} = 52.0 - 0.0 - 0.0 - 0.0 - 0.0 = 52.0\ \text{mi/h}$$

AR0073702

Step 3: Select FFS Curve

Despite the fact that slight differences in FFS exist, all three segment analyses will use the 50-mi/h speed–flow curve.

Step 4: Adjust Demand Volume

Demand volume is adjusted by using Equation 14-3:

$$v_p = \frac{V}{PHF \times N \times f_{HV} \times f_p}$$

where

V = 1,500 veh/h (given),

PHF = 0.90 (given),

N = 2 lanes (given), and

f_p = 1.00 (familiar users, given).

To compute the heavy-vehicle adjustment factor (Equation 14-4), PCEs for trucks are needed for (a) level terrain, (b) a 4%, 6,500-ft upgrade, and (c) a 4%, 6,000-ft downgrade. The following values are obtained:

- Level terrain: 1.5 (Exhibit 14-12);
- Upgrade: 3.0 (Exhibit 14-13, with 6% trucks and a 4% grade, 0.00105,280 = 1.14 mi), and
- Downgrade: 1.5 (Exhibit 14-13 with a 4% grade less than 4 mi long).

As in Example Problem 1, the downgrade equivalent is the same as the equivalent for level terrain. Therefore, there are only two heavy-vehicle adjustment factors (Equation 14-4):

$$f_{HV}\text{ (level,down)} = \frac{1}{1 - 0.06(1.5 - 1)} = 0.971$$

$$f_{HV}\text{ (up)} = \frac{1}{1 - 0.06(3.0 - 1)} = 0.893$$

and

$$v_p\text{(level, down)} = \frac{1500}{0.90 \times 2 \times 0.971 \times 1.0} = 858\text{ pc/mi/ln}$$

$$v_p\text{ (up)} = \frac{1500}{0.90 \times 2 \times 0.893 \times 1.0} = 933\text{ pc/mi/ln}$$

Step 5: Estimate Speed and Density

Speed is estimated by using the equations of Exhibit 14-3 or the graph in Exhibit 14-3. With the equations of Exhibit 14-3, both demand flow rates are less than 1,400 pc/h/ln. Therefore, the speeds are equal to the FFSs, both of which are 50 mi/h.

AR0073703

Density is computed by using Equation 14-5.

$$D\ (\text{level, down}) = \frac{858}{50} = 17.1\ \text{pc/mi/ln}$$

$$D\ (\text{up}) = \frac{933}{50} = 18.7\ \text{pc/mi/ln}$$

Step 6: Determine LOS

The LOS is found by comparing the densities of the segments with the criteria in Exhibit 14-4. The level terrain and downgrade segments operate at LOS B. The upgrade segment operates at LOS C.

Discussion

Even though the upgrade technically operates at LOS C, it is very close to the LOS B boundary (18.0 pc/mi/ln). All segments of the multilane highway facility described operate well. No remediation would likely be needed.

EXAMPLE PROBLEM 3: DESIGN CROSS SECTION REQUIRED TO PROVIDE TARGET LOS

A new 2-mi segment of multilane highway will be built within a 150-ft right-of-way. Sixty feet of right-of-way will be reserved for clear zones; therefore, 90 ft of width will be available for travel lanes, shoulders, and median. How many travel lanes are needed to provide LOS D during the peak hour?

The Facts

- AADT = 60,000 veh/day;
- D = 0.10; K = 0.55;
- 55-mi/h speed limit;
- Rolling terrain;
- Traffic composition: 5% trucks, no RVs;
- PHF = 0.90;
- Access-point density = 10.0 access points/mi; and
- Familiar facility users.

Comments

This problem is potentially iterative. The exact cross section is unknown—not only the number of lanes but also the lateral clearances and median treatment. Thus, assumptions will be made and will have to be checked when the final analysis is complete. To begin the solution, it will be assumed that 12-ft lanes will be provided and that 6-ft clearances at the roadside and median will also be provided (TLC = 6 + 6 = 12 ft). A divided highway will also be assumed for initial computations.

Step 1: Input Data

All input data are specified in the example problem statement.

AR0073704

Step 2: Compute FFS

No BFFS is given. It will be assumed that the BFFS will be 5 mi/h more than the posted speed limit, or 50 + 5 = 55 mi/h. FFS is estimated by using Equation 14-1. Given that the lane width, lateral clearance, and median treatments assumed are all base conditions, there is no adjustment for these. The only adjustment is for access point density. On the basis of Exhibit 14-11 for 10 access points/mi, the adjustment is 2.5 mi/h. Therefore

$$FFS = BFFS - f_{LW} - f_{LC} - f_M - f_A$$

$$FFS = 55.0 - 0.0 - 0.0 - 0.0 - 2.5 = 52.5 \text{ mi/h}$$

Step 3: Select FFS Curve

Following this chapter's guidelines, for a FFS of 52.5 mi/h, the 55-mi/h base speed flow curve will be used in this analysis.

Step 4: Determine Number of Lanes Needed for LOS D

Step 4 has a number of intermediate computations. First, the demand volume is stated as an AADT. This volume must be converted to an estimated directional design-hour volume ($V = DDHV$) by using Equation 14-9.

$$V = DDHV = AADT \times K \times D$$

$$V = DDHV = 60{,}000 \times 0.10 \times 0.55 = 3{,}300 \text{ veh/h}$$

The number of lanes required to meet a target LOS is estimated with Equation 14-8.

$$N = \frac{V}{MSF \times PHF \times f_{HV} \times f_p}$$

where

MSF = 1,850 pc/h/ln (Exhibit 14-17, with LOS D and 55 mi/h),

PHF = 0.90 (given), and

f_p = 1.00 (familiar users).

The heavy-vehicle adjustment factor is estimated by using Equation 14-4 and the PCE for trucks on rolling terrain from Exhibit 14-12, which is 2.5. Thus

$$f_{HV} = \frac{1}{1 + 0.05(2.5 - 1)} = 0.930$$

and

$$N = \frac{3{,}300}{1{,}850 \times 0.90 \times 0.93 \times 1.00} = 2.13 \text{ lanes}$$

This result means that to meet the criteria for LOS D within the peak hour, three lanes in each direction will have to be provided and the facility will be a six-lane multilane highway.

It is necessary to consider whether the assumed cross section (now known to be six lanes) can fit in the 96 ft available width. Lane widths are 12 ft, which fit

AR0073705

lateral clearances at both roadsides and in the median. If a 12-ft median is assumed, the total width becomes (6 × 12) + (6 × 2) = 12 + 72 + 12 + 12 = 96 ft, which is in excess of the 90-ft right-of-way.

The median treatment could be reconsidered. It is not necessary to have a 12-ft median with 6-ft clearances to the inside edges of the travel pavement to produce the desired operation. A concrete median barrier with 2-ft buffers on each side would occupy a total of only 4 ft and would not be expected to have any impact on driver behavior or the LOS. Then the total width required would be (6 × 12) + (6 × 2) + 4 = 88 ft. This is the design cross section. None of the calculations done to this point would be altered by this change.

It is likely that providing a six-lane highway will result in better operations than the minimum of LOS D. With three lanes shown, the demand flow rate under base conditions can be computed with Equation 14-3:

$$v_p = \frac{3{,}300}{0.90 \times 3 \times 0.93 \times 1.00} = 1{,}314 \text{ pc/h/ln}$$

Step 5: Estimate Speed and Density

The speed of the traffic stream can be determined by using the equations of Exhibit 14-2 or the graph in Exhibit 14-3. On the basis of the equations, because the demand flow rate is less than 1,400 pc/h/ln, the speed is the FFS, or 55 mi/h in this case.

The density may now be computed by using Equation 14-5:

$$D = \frac{1{,}314}{55} = 23.9 \text{ pc/mi/ln}$$

Step 6: Determine LOS

From the criteria of Exhibit 14-4, the LOS provided is C, one grade better than the design target of LOS D.

Discussion

The design method in a greenfield cross section on a divided multilane highway with no clearance obstructions. The LOS provided is better than the design target, since three lanes were provided in each direction while only 2.13 lanes were necessary.

EXAMPLE PROBLEM 4: MULTILANE HIGHWAY MODERNIZATION

A 2.5-mi segment of a substandard multilane highway is to be improved by providing wider shoulders, widening the lanes to 12 ft, improving the alignment on a few sharp curves, restricting the number of roadside access points, and adding a median. These improvements will increase the FFS of the facility from 50 mi/h to 60 mi/h. How much additional traffic can be accommodated while the post-improvement LOS is maintained?

The Facts

- Demand flow rate = 1,400 pc/h/ln under base conditions.

AR0073706

Comments

This problem is relatively straightforward. Most of the steps in a standard analysis can be skipped, since the present and future FFS are given, and the demand flow rate has already been reduced to base conditions.

Step 1: Find Existing LOS

With the equations of Exhibit 14-3, the speed of vehicles in the existing configuration will be the FFS, or 50 mi/h. With Equation 14-5, the density is computed as

$$D = \frac{1{,}400}{50} = 28 \text{ pc/mi/ln}$$

From Exhibit 14-4, this is LOS D.

Step 2: Find Expected LOS After Improvement

With the equations of Exhibit 14-3, the speed of vehicles on the improved cross section will also be the FFS, or 60 mi/h. The density is computed with Equation 14-5.

$$D = \frac{1{,}400}{60} = 23.2 \text{ pc/mi/ln}$$

From Exhibit 14-4, this is LOS C.

Step 3: Find Additional Volume Under LOS C

From Exhibit 14-5, the maximum service flow rate for LOS C on a 60-mi/h multilane highway is 1,550 pc/h/ln. The existing demand flow rate is 1,400 pc/h/ln. The additional demand flow possible while LOS C is maintained is 1,550 − 1,400 = 150 pc/h/ln. Since there are three lanes in each direction, the demand flow rate can increase by 3 × 150 = 450 pc/h without slipping into LOS D.

Discussion

This example problem illustrates how the methodology can be adapted to different uses, in this case, evaluating the impact of a proposed improvement to a multilane highway. The LOS improves from D to C, and an additional peak-hour demand flow rate of 450 pc/h can be accommodated by the improved highway while LOS C is maintained.

EXAMPLE PROBLEM 5: FUTURE CROSS SECTION REQUIRED TO PROVIDE TARGET LOS

A new suburban multilane highway is being planned. The opening-day forecast AADT is 42,000 vehicles per day. How many lanes will be needed to provide for LOS C during the peak hour on opening day?

The Facts

Since this is a planning application, many details cannot be based on current information. As a result, some of the "facts" are forecasts, and default values based on regional data are used to complete the list of facts needed for the analysis.

AR0073707

- Demand = 40,000 veh/day;
- K = 0.10; D = 0.60;
- Traffic composition: 10% trucks, no RVs;
- Rolling terrain;
- Base FFS = 55 mi/h;
- Lane width = 12 ft; roadside lateral clearance = 6 ft;
- Undivided highway;
- Access point density = 6 access points/mi;
- PHF = 0.90; and
- Commuter traffic.

Comments

The demand volume, given as an AADT, must be converted to a DDHV. Once this is done, the example becomes a design application to determine the number of lanes needed to deliver LOS C.

Step 1: Input Data

All input data for this problem are specified in the problem statement.

Step 2: Compute FFS

The FFS is computed by using Equation 14-1. The BFFS is given. Lane widths and lateral clearances conform to base conditions, and no adjustments will be necessary. Then

$$FFS = BFFS - f_{LW} - f_{LC} - f_M - f_A$$

where

$BFFS$ = 55 mi/h (given);

f_{LW} = 0.0 mi/h (Exhibit 14-8, with 12-ft lanes);

f_{LC} = 0.0 mi/h (Exhibit 14-9, with 6-ft clearances);

f_M = 1.6 mi/h (Exhibit 14-10, undivided);

f_A = 1.5 mi/h (Exhibit 14-11, with 6 access points/mi, interpolated);

and

$$FFS = 55.0 - 0.0 - 0.0 - 1.6 - 1.5 = 51.9 \text{ mi/h}$$

Step 3: Select FFS Curve

On the basis of criteria given in the methodology section, the 50-mi/h FFS curve will be used for this solution.

Step 4: Determine Number of Lanes Needed to Provide LOS C

The number of lanes needed to deliver LOS C on opening day is estimated with Equation 14-5.

AR0073708

$$N = \frac{V}{MSF_i \times PHF \times f_{HV} \times f_p}$$

The demand volume must be converted to an hourly basis by using Equation 14-9:

$$V = DDHV = AADT \times K \times D$$

$$V = DDHV = 42{,}000 \times 0.10 \times 0.60 = 2{,}520 \text{ veh/h}$$

The value of MSF is selected from Exhibit 14-17 for a 50-mi/h highway and LOS C: 1,300 pc/h. The heavy-vehicle adjustment factor f_{HV} is computed by using Equation 14-4 with a PCE of 2.5 selected from Exhibit 14-12 for trucks on rolling terrain:

$$f_{HV} = \frac{1}{1 + 0.10(2.5 - 1)} = 0.870$$

Because the demand volume is composed primarily of commuters, the adjustment factor for driver population f_p is 1.00. The PHF was given as 0.90. Then

$$N = \frac{2{,}520}{1{,}300 \times 0.90 \times 0.87 \times 1.00} = 2.48 \text{ lanes}$$

This result implies that a six-lane cross section will have to be provided. Because this cross section is more than the minimum computed, the actual demand flow rate under base conditions should be computed by using Equation 14-3:

$$v_p = \frac{2{,}520}{0.90 \times 3 \times 0.87 \times 1.00} = 1{,}073 \text{ pc/mi/ln}$$

Step 5: Estimate Speed and Density

From the equations of Exhibit 14-5, the expected speed for the demand flow rate is the FFS of 50 mi/h. The density can now be computed with Equation 14-5:

$$D = \frac{1{,}073}{50} = 21.5 \text{ pc/mi/ln}$$

Step 6: Determine LOS

From Exhibit 14-4, the six-lane multilane highway will be expected to operate at LOS C, which was the design objective.

Discussion

In this case, the target LOS has been achieved with the six-lane cross section. The highway will, however, operate in the better portion of LOS C instead of at the boundary.

1. INTRODUCTION

VOLUME 2: UNINTERRUPTED FLOW
10. Freeway Facilities
11. Basic Freeway Segments
13. Freeway Weaving Segments
14. Freeway Ramp and Diverge Segments
14. Multilane Highways
15. Two-Lane Highways

Two-lane highways have one lane for the use of traffic in each direction. The principal characteristic that separates minor vehicle traffic on two-lane highways from other uninterrupted-flow facilities is that passing maneuvers take place in the opposing lane of traffic. Passing maneuvers are limited by the availability of gaps in the opposing traffic stream and by the availability of sufficient sight distance for a driver to discern the approach of an opposing vehicle safely. As demand flows and geometric restrictions increase, opportunities to pass decrease. This creates platoons within the traffic stream, with trailing vehicles subject to additional delay because of the inability to pass the lead vehicles.

Two-lane highways have one lane for the use of traffic in each direction. Passing takes place in the opposing lane of traffic when sight distance is adequate and safe gaps in the opposing traffic stream are available.

Because passing capacity decreases as passing demand increases, two-lane highways exhibit a unique characteristic: operating quality often decreases precipitously as demand flow increases, and operations can become "unacceptable" at relatively low volume-to-capacity ratios. For this reason, few two-lane highways ever operate at flow rates approaching capacity; in most cases, poor operating quality has led to improvements or reconstruction long before capacity demand is reached.

The quality of service for bicyclists is primarily affected by the speed and volume of adjacent traffic flows and by the degree of separation between bicyclist and motor vehicle traffic allowed by the roadway geometry.

Chapter 15, Two-Lane Highways, presents methodologies for the analysis, design, and planning of two-lane highway facilities operating under uninterrupted flow, for both automobiles and bicycles. Uninterrupted flow exists when there are no traffic control devices that interrupt traffic and where no platoons are formed by upstream signals. In general, any segment that is 2.0 to 3.0 mi from the nearest signalized intersection would fit into this category. Where signalized intersections are less than 2.0 mi apart, the facility should be classified as an urban street and analyzed with the methodologies of Chapter 16, Urban Street Facilities, and Chapter 17, Urban Street Segments, which are located in Volume 3. It is assumed that no passing in the opposing lane occurs on urban streets.

Chapter 15 also includes a methodology for predicting the effect of passing and truck climbing lanes on two-lane highways.

CHARACTERISTICS OF TWO-LANE HIGHWAYS

Functions of Two-Lane Highways in Highway Systems

Two-lane highways are a key element in the highway systems of most states and counties. They are located in many different geographical areas and serve a wide variety of traffic functions. Two-lane highways also serve a number of bicycle trips, particularly recreational trips. Any consideration of operating quality criteria must account for these disparate functions.

AR0073715

The functions of two-lane highways include efficient mobility, accessibility, scenic and recreational enjoyment, and service to small towns and communities.

Efficient mobility is the principal function of major two-lane highways that connect major trip generators or that serve as primary links in state and national highway networks. These routes tend to serve long-distance commercial and recreational travelers, and long sections may pass through rural areas without traffic control interruptions. Consistent high-speed operations and infrequent passing delays are desirable for these types of facilities.

Other paved, two-lane rural highways primarily provide accessibility to remote or sparsely populated areas. Such highways provide reliable all-weather access and often serve low traffic demands. Cost-effective access is a primary concern. Although high speed is beneficial, it is not the principal objective. Delay, as indicated by the formation of platoons, is a more relevant measure of service quality.

Two-lane roads also serve *scenic and recreational* areas in which the vista and environment are meant to be experienced and enjoyed without traffic interruption or delay. High-speed operation is neither expected nor desired. Passing delays, however, significantly distract from the scenic enjoyment of trips and should be minimized whenever possible.

Two-lane roads may also pass through and serve *small towns and communities*. Such areas have higher density development than would normally be expected along a rural highway, and speed limits in these areas are often lower. In these cases, drivers expect to be able to maintain speeds close to the posted limit. Since two-lane highway segments serving such developed areas are usually of limited length, passing delays are not a significant issue.

Two-lane highways serve a wide range of functions and serve a variety of rural areas, as well as more developed areas. Therefore, this chapter's methodology and level of service (LOS) criteria provide flexibility to encompass the resulting range of driver expectations.

Classification of Two-Lane Highways

Because of the wide range of functions served by two-lane highways, the automobile methodology establishes three classes of highways.

The first two classes address *rural two-lane highways*. The methodology for them was developed as part of National Cooperative Highway Research Program (NCHRP) Project 3-55(3) in 1999 (1) and revised as part of NCHRP Project 20-7(160) in 2008 (2).

The third class addresses two-lane highways in *developed areas*. The analysis approach for these highways is a modification of the rural highway method noted previously and was developed by the Florida Department of Transportation (FDOT) (3). This modification has not been subjected to a national calibration study and is based on the procedure developed and adopted by FDOT. It is presented here as an alternative procedure, since it is based entirely on information collected in Florida. For clarity, however, the material is integrated into the overall presentation and is not discussed separately as an alternative procedure.

AR0073716

The three classes of two-lane highways are defined as follows:

- *Class I two-lane highways* are highways where motorists expect to travel at relatively high speeds. Two-lane highways that are major intercity routes, primary connectors of major traffic generators, daily commuter routes, or major links in state or national highway networks are generally assigned to Class I. These facilities serve mostly long-distance trips or provide the connections between facilities that serve long-distance trips.
- *Class II two-lane highways* are highways where motorists do not necessarily expect to travel at high speeds. Two-lane highways functioning as access routes to Class I facilities, serving as scenic or recreational routes (and not as primary arterials), or passing through rugged terrain (where high-speed operation would be impossible) are assigned to Class II. Class II facilities most often serve relatively short trips, the beginning or ending portions of longer trips, or trips for which sightseeing plays a significant role.
- *Class III two-lane highways* are highways serving moderately developed areas. They may be portions of a Class I or Class II highway that pass through small towns or developed recreational areas. On such segments, local traffic often mixes with through traffic, and the density of unsignalized roadside access points is noticeably higher than in a purely rural area. Class III highways may also be longer segments passing through more spread-out recreational areas, also with increased roadside densities. Such segments are often accompanied by reduced speed limits that reflect the higher activity level.

Exhibit 15-1 shows examples of the three classes of two-lane highway.

The definition of two-lane highway classes is based on their function. Most arterials or trunk roads are considered to be Class I highways, while most collectors and local roads are considered to be Class II or Class III highways. The primary determinant of a facility's classification is the motorist's expectation, which might not agree with the overall functional category of the route. For example, a major intercity route passing through a rugged mountainous area might be described as Class II if drivers recognize that high-speed operation is not feasible due to the terrain, but the route could still be considered to be in Class I.

Even Class III highways incorporate only uninterrupted-flow segments of two-lane highways. Occasional signalized or unsignalized intersections on any two-lane highway must be separately analyzed with the appropriate *Highway Capacity Manual* (HCM) methodologies in Chapter 18, Signalized Intersections, Chapter 20, All-Way STOP-Controlled Intersections, or Chapter 21, Roundabouts. The results must be carefully considered in conjunction with those of uninterrupted-flow portions of the facility to obtain a complete picture of probable operations.

AR0073717

Exhibit 15-1

Classification Illustrated

(a) Examples of Class I Two-Lane Highways

(b) Examples of Class II Two-Lane Highways

(c) Examples of Class III Two-Lane Highways

Base Conditions

The base conditions for two-lane highways are the absence of restrictive geometric, traffic, or environmental factors. Base conditions are not the same as typical or default conditions, both of which may reflect common restrictions. Base conditions are closer to what may be considered as ideal conditions (i.e., the best conditions that can be expected given normal design and operational practice). The methodology of this chapter accounts for the effects of geometric, traffic, and environmental factors that are more restrictive than the base conditions. The base conditions for two-lane highways are as follows:

- Lane widths greater than or equal to 12 ft,
- Clear shoulders wider than or equal to 6 ft,
- No no-passing zones,
- All passenger cars in the traffic stream,

AR0073718

- Level terrain, and
- No impediments to through traffic (e.g., traffic signals, turning vehicles).

Traffic can operate ideally only if lanes and shoulders are wide enough not to constrain speeds. Lanes narrower than 12 ft and shoulders narrower than 6 ft have been shown to reduce speeds, and they may increase percent time-spent-following (PTSF) as well.

The length and frequency of no-passing zones are a result of the roadway alignment. No-passing zones may be marked by barrier centerlines in one or both directions, but any segment with a passing sight distance of less than 1,000 ft should also be considered to be a no-passing zone.

On a two-lane highway, passing in the opposing lane of flow may be necessary. It is the only way to fill gaps forming in front of slower-moving vehicles in the traffic stream. Restrictions on the ability to pass significantly increase the rate at which platoons form in the traffic stream, since motorists are unable to pass slower vehicles in front of them.

Basic Relationships

Exhibit 15-2 shows the relationships among flow rate, average travel speed (ATS), and PTSF for an extended directional segment of two-lane highway under base conditions. While the two directions of flow interact on a two-lane highway (because of passing maneuvers), the methodology of this chapter analyzes each direction separately.

Exhibit 15-2(b) illustrates a critical characteristic that affects two-lane highways. Low directional volumes create high values of PTSF. With only 400 pc/h, PTSF ranges from 60% (with 200 pc/h opposing flow) to almost 80% (with 1,600 pc/h opposing flow).

In multilane uninterrupted flow, typically acceptable speeds can be maintained at relatively high proportions of capacity. On two-lane highways, service quality (as measured by PTSF) begins to deteriorate at relatively low demand flows.

CAPACITY AND LOS

Capacity

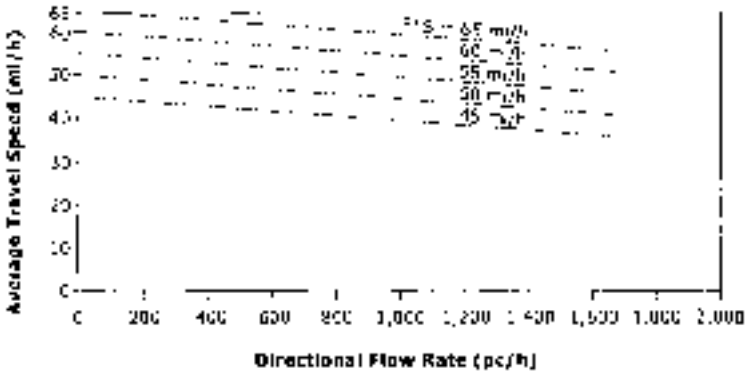
The capacity of a two-lane highway under base conditions is 1,700 pc/h in one direction, with a limit of 3,200 pc/h for the total of the two directions. Because of the interactions between directional flows, when a capacity of 1,700 pc/h is reached in one direction, the maximum opposing flow would be limited to 1,500 pc/h.

Capacity of a two-lane highway under base conditions is 1,700 pc/h in one direction, with a maximum of 3,200 pc/h in the two directions.

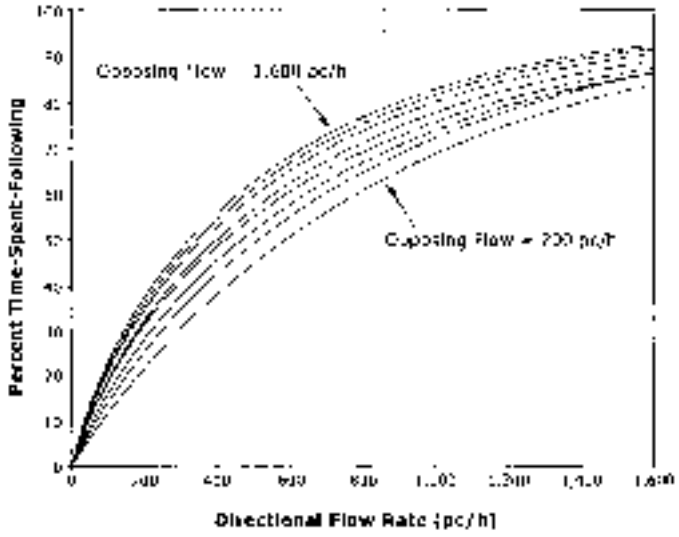
Capacity conditions, however, are rarely observed—except in short segments. Because service quality deteriorates at relatively low demand flow rates, most two-lane highways are upgraded before demand approaches capacity.

AR0073719

Exhibit 15-2
Speed, Flow, and PTSF Relationships for Directional Segments with Base Conditions



(a) ATS Versus Directional Flow Rate



(b) PTSF Versus Directional Flow Rate

Capacity is important for evacuation and special event planning

However, estimation of capacity conditions is important for evacuation planning, special event planning, and evaluation of the downstream impacts of incident bottlenecks once cleared.

Two-way flow rates as high as 3,200 pc/h can be observed for short segments fed by high demands from multiple or multilane facilities. This may occur at tunnels or bridges, for example, but such flow rates cannot be expected over extended segments.

Capacity is not defined for bicycles on two-lane highways because of lack of data. Bicycle volumes approaching capacity do not often occur on two-lane highways except during special bicycle events, and little information is available on which to base a definition.

AR0073720

Levels of Service

Automobile Mode

Because of the wide range of situations in which two-lane highways are found, three measures of effectiveness are incorporated into the methodology of this chapter to determine automobile LOS.

1. *ATS* reflects mobility on a two-lane highway. It is defined as the highway segment length divided by the average travel time taken by vehicles to traverse it during a designated time interval.
2. *PTSF* represents the freedom to maneuver and the comfort and convenience of travel. It is the average percentage of time that vehicles must travel in platoons behind slower vehicles due to the inability to pass. Because this characteristic is difficult to measure in the field, a surrogate measure is the percentage of vehicles traveling at headways of less than 3.0 s at a representative location within the highway segment. PTSF also represents the approximate percentage of vehicles traveling in platoons.
3. *Percent of free-flow speed* (PFFS) represents the ability of vehicles to travel at or near the posted speed limit.

On Class I two-lane highways, speed and delay due to passing restrictions are both important to motorists. Therefore, on these highways, LOS is defined in terms of both ATS and PTSF. On Class II highways, travel speed is not a significant issue to drivers. Therefore, on these highways, LOS is defined in terms of PTSF only. On Class III highways, high speeds are not expected. Because the length of Class III segments is generally limited, passing restrictions are also not a major concern. In these cases, drivers would like to make steady progress at or near the speed limit. Therefore, on these highways, PFFS is used to define LOS. The LOS criteria for two-lane highways are given in Exhibit 15-3.

Exhibit 15-3
Automobile LOS for Two-Lane Highways

LOS	Class I Highways ATS (mi/h)	Class I Highways PTSF (%)	Class II Highways PTSF (%)	Class III Highways PFFS (%)
A	>55	≤35	≤40	>91.7
B	>50–55	>35–50	>40–55	>83.3–91.7
C	>45–50	>50–65	>55–70	>75.0–83.3
D	>40–45	>65–80	>70–85	>66.7–75.0
E	≤40	>80	>85	≤66.7

Because driver expectations and operating characteristics on the three categories of two-lane highways are quite different, it is difficult to provide a single definition of operating conditions at each LOS.

Two characteristics, however, have a significant impact on actual operations and driver perceptions of service.

- *Passing capacity*: Since passing maneuvers on two-lane highways are made in the opposing direction of flow, the ability to pass is limited by the opposing flow rate and by the distribution of gaps in the opposing flow.
- *Passing demand*: As passing and PTSF are related in a given direction, the demand for passing maneuvers increases. As more drivers are caught in a

AR0073721

platoon behind a slow-moving vehicle, they will desire to make more passing maneuvers.

Both passing capacity and passing demand are related to flow rates. If flow in both directions increases, a difficult trend is established: as passing demand increases, passing capacity decreases.

At LOS A, motorists experience high operating speeds on Class I highways and little difficulty in passing. Platoons of three or more vehicles are rare. On Class II highways, speed would be controlled primarily by roadway conditions. A small amount of platooning would be expected. On Class III highways, drivers should be able to maintain operating speeds close or equal to the free-flow speed (FFS) of the facility.

At LOS B, passing demand and passing capacity are balanced. On both Class I and Class II highways, the degree of platooning becomes noticeable. Some speed reductions are present on Class I highways. On Class III highways, it becomes difficult to maintain FFS operation, but the speed reduction is still relatively small.

At LOS C, most vehicles are traveling in platoons. Speeds are noticeably curtailed on all three classes of highway.

At LOS D, platooning increases significantly. Passing demand is high on both Class I and II facilities, but passing capacity approaches zero. A high percentage vehicles are now traveling in platoons, and PTSF is quite noticeable. On Class III highways, the fall-off from FFS is now significant.

At LOS E, demand is approaching capacity. Passing on Class I and II highways is virtually impossible, and PTSF is more than 80%. Speeds are seriously curtailed. On Class III highways, speed is less than two-thirds the FFS. The lower limit of this LOS represents capacity.

LOS F occurs whenever demand flow in one or both directions exceeds the capacity of the segment. Operating conditions are unstable, and heavy congestion exists on all classes of two-lane highway.

Bicycle Mode

Bicycle LOS is based on a traveler-perception model.

Bicycle levels of service for two-lane highway segments are based on a bicycle LOS (BLOS) score, which is in turn based on a traveler-perception model. This score is based, in order of importance, on five variables:

- Average effective width of the outside through lane,
- Motorized vehicle volumes,
- Motorized vehicle speeds,
- Heavy vehicle (truck) volumes, and
- Pavement condition.

The LOS ranges for bicycles on two-lane highways are given in Exhibit 15-4. The same LOS score is used for multilane highways, as described in Chapter 14.

AR0073722

LOS	BLOS Score
A	≤1.5
B	>1.5–2.5
C	>2.5–3.5
D	>3.5–4.5
E	>4.5–5.5
F	>5.5

Exhibit 15-4
Bicycle LOS for Two-Lane Highways

REQUIRED INPUT DATA AND DEFAULT VALUES

Exhibit 15-5 lists the information necessary to apply the methodology. It also contains suggested default values for use when segment-specific information is not available. The user is cautioned, however, that every use of a default value instead of a field-measured, segment-specific variable makes the analysis results more approximate and less related to the specific conditions that describe the study site. Defaults should be used only when field measurements cannot be collected.

Required Data	Recommended Default Value	Relevant Modes
Geometric Data		
Highway class	Must select as appropriate	Auto
Lane width	12 ft	Auto, bicycle
Shoulder width	6 ft	Auto, bicycle
Access-point density (one side)	Class I and II: 8/mi, Class III: 16/mi	Auto
Terrain	Level or rolling	Auto
Percent no-passing zone[a]	Level: 20%, rolling: 40%, mountainous: 80%	Auto
Speed limit	Speed limit	Bicycle
Base design speed	Speed limit + 10 mi/h	Auto
Length of passing lane (if present)	Must be site-specific	Auto
Pavement condition	1 on FHWA 5-point rating scale (good)	Bicycle
Demand Data		
Hourly automobile volume	Must be site-specific	Auto, bicycle
Length of analysis period	15 min (0.25 h)	Auto, bicycle
Peak hour factor	0.88	Auto, bicycle
Directional split	50/50	Auto, bicycle
Heavy vehicle percentage[b]	6% trucks	Auto, bicycle
Percent occupied on-highway parking	0%	Bicycle

Notes: [a] Percent no-passing zone may be different in each direction.
[b] See Chapter 25 in Volume 4 for more specific default values on vehicle percentages.

Exhibit 15-5
Required Input Data and Default Values for Two-Lane Highways

The use of some default values is less problematic than others. Lane and shoulder widths of 12 and 6 ft, respectively, are common, particularly on Class I highways. However, these variables have large impacts on bicycle LOS, increasing the importance of segment-specific data. A general assessment of terrain is usually straightforward and requires only general knowledge of the area through which the highway is built. Access-point densities are more difficult and tend to vary widely on a site-by-site basis. Estimating the percent no-passing zones on the basis of a generalized assessment of terrain is also challenging, since the details of vertical and horizontal alignment can have a significant impact on this factor.

FFS is best measured at the site or at a similar site. While adjustments to a base free-flow speed (BFFS) are provided as part of the methodology, no firm guidance on determining the BFFS is given. The default suggestions of Exhibit 15-5 are highly approximate.

AR0073723

In terms of demand data, the length of the analysis period is a recommended HCM standard of 15 min (although longer periods can be examined). The peak hour factor (PHF) is typical but could vary significantly on the basis of localized trip generation characteristics. The directional split is best observed directly, since it can vary widely over time, even at the same location. The recommended default for heavy vehicle presence is also highly approximate. This factor varies widely with local conditions; Chapter 26, Freeway and Highway Segments: Supplemental, provides state-specific default values (6).

As is the case with all default values, these values should be used with care, and only when site-specific data cannot be acquired by any reasonable means.

DEMAND VOLUMES AND FLOW RATES

Demand volumes are generally stated in vehicles per hour under prevailing conditions. They are converted in the methodology to demand flow rates in passenger cars per hour under base conditions. The PHF, in particular, is used to convert hourly volumes to flow rates.

If demand volumes are measured in 15-min increments, use of the PHF to convert to flow rates is unnecessary. The worst 15 min period is selected, and flow rates are the 15-min volumes multiplied by 4. When this is done, the PHF is set at 1.00 for the rest of the application.

In measuring demand volumes or flow rates, flow may be restricted by upstream bottlenecks or even signals that are more than 2 mi away from the study site (if they are closer, this methodology is not applicable). Downstream congestion may also affect flows in a study segment. Insofar as is possible, demand volumes and flow rates should reflect the situation that would exist with no upstream or downstream limiting factors.

AR0073724

2. METHODOLOGY

This section presents the details of the methodology for two-lane highways and discusses its use in planning and operational analysis applications.

SCOPE OF THE METHODOLOGY

This chapter presents an operational analysis methodology for directional segments of two-lane highways for automobiles and bicyclists. Both directions may be analyzed separately on the facility as segments to obtain a full estimate of operating conditions.

This chapter's automobile methodology addresses the analysis of

- Directional segments in general terrain (level or rolling),
- Directional segments on specific grades, and
- Directional segments including passing and truck climbing lanes.

All segments in mountainous terrain, and all grades of 3% or more that cover a length of 0.6 mi or more, must be analyzed as specific grades.

The methodology is most directly used to determine the LOS on a uniform directional segment of two-lane highway by estimating the measures of effectiveness that define LOS (ATS, PTSF, PFFS). Such an analysis can also be used to determine the capacity of the directional segment or the service flow rate that can be accommodated at any given LOS.

This chapter includes an appendix that addresses specialized treatments for two-lane highways that cannot be evaluated with the basic methodology. Special procedures are also provided to determine the impact of passing lanes or truck climbing lanes on two-lane highway segments.

LIMITATIONS OF THE METHODOLOGY

The operational analysis methodologies in this chapter do not address two-lane highways with signalized intersections. Isolated signalized intersections on two-lane highways may be evaluated with the methodology of Chapter 18, Signalized Intersections. Two-lane highways in urban and suburban areas with multiple signalized intersections 2 mi or less apart should be analyzed as urban streets or arterials with the methodology of Chapter 17, Urban Street Segments.

The bicycle methodology was developed with data collected on urban and suburban streets, including facilities that would be defined as suburban two-lane highways. Although the methodology has been successfully applied to rural two-lane highways in different parts of the United States, users should be aware that conditions on many rural two-lane highways will be outside the range of values used to develop the bicycle LOS model. The ranges of values used in the development of the bicycle LOS model [7] are shown below:

- Width of the outside through lane: 10 to 16 ft;
- Shoulder width: 0 to 6 ft;

AR0073725

- Motorized vehicle volumes: up to 36,000 annual average daily traffic (AADT);
- Posted speed: 45 to 50 mi/h;
- Heavy vehicle percentage: 0% to 2%; and
- Pavement condition: 1 to 5 on the Federal Highway Administration (FHWA) 5-point pavement rating scale.

The bicycle LOS methodology also does not take differences in prevalent driver behavior into consideration, although driver behavior may vary considerably both regionally and by facility. In particular, the likelihood of drivers slowing down or providing additional horizontal clearance while passing cyclists plays a significant role in the perceived quality of service of a facility.

AUTOMOBILE MODE

Overview

Exhibit 15-6 illustrates the basic steps in the methodology for two-lane highways. Because the three classes of highways use different service measures to determine LOS, not all steps are applied to each class of facility.

Note that the computational step for estimating ATS applies only to Class I and Class III highways, while the step for estimating PTSF applies only to Class I and Class II highways. The step for estimating PFFS applies only to Class III highways.

Segments for Analysis

The methodology of this chapter applies to uniform directional segments of two-lane highway. While the two directions of flow interact through passing maneuvers (and limitations on passing maneuvers), each direction must be analyzed separately.

Uniform segments have the same or similar traffic and roadway conditions. Segment boundaries should be established at points where a change occurs in any of the following: terrain, lane width, shoulder width, facility classification, or demand flow rate.

AR0073726

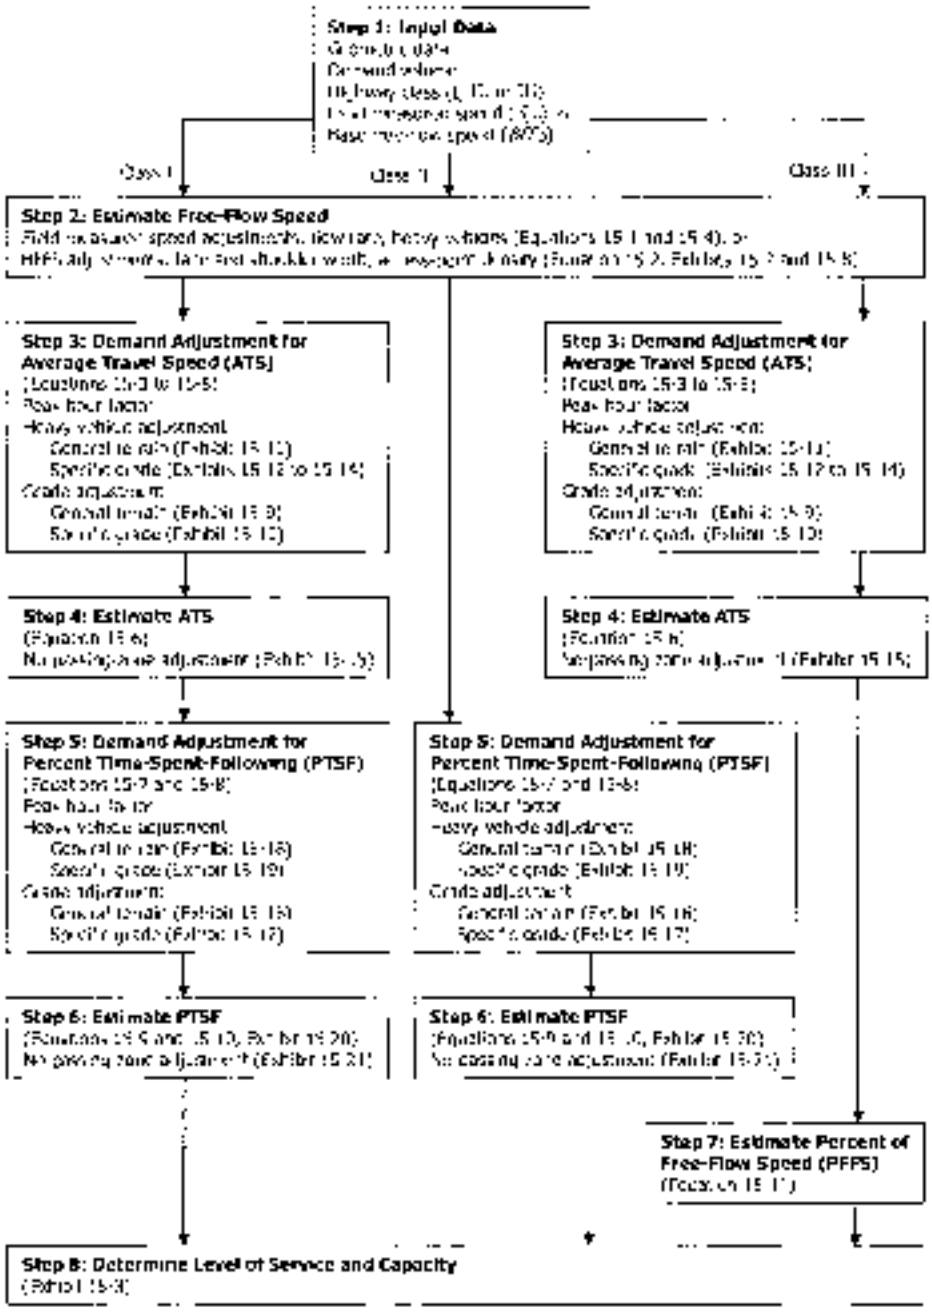


Exhibit 15-6
Flowchart of the Two-Lane Highway Methodology

Computational Steps

Step 1: Input Data

Exhibit 15-5 lists the information that must be available before a two-lane highway segment can be analyzed. The exhibit also lists default values suggested for use when site-specific data are not available.

AR0073727

Step 3: Estimate the FFS

A key step in the analysis of a two-lane highway is the determination of the FFS for the segment. There are three ways to estimate FFS.

Direct Field Measurement

Direct field measurement on the subject highway segment is preferred. Measurements should be taken only in the direction under analysis; if both directions are to be analyzed, then separate measurements in each direction are made. Each directional measurement should be based on a random sample of at least 100 vehicle speeds. The FFS can be directly measured as the mean speed under low-demand conditions (i.e., the two-way flow rate is less than or equal to 200 veh/h).

If the analysis segment cannot be directly observed, then measurements from a similar facility (same highway class, same speed limit, similar environment, etc.) may be used.

Field Measurements at Higher Flow Rates

For some highways, it may be difficult or impossible to observe total flow rates less than 200 veh/h. In such cases, a speed sample may be taken at higher flow rates and adjusted accordingly. The same sampling approach is taken: each direction is separately observed, with each directional sample including at least 100 observed speeds. The measured mean speed is then adjusted with Equation 15-1.

Equation 15-1

$$FFS = S_{FM} + 0.00776\left(\frac{v}{f_{HV,ATS}}\right)$$

where

FFS = free-flow speed (mi/h);

S_{FM} = mean speed of sample in > 200 veh/h (mi/h);

v = total demand flow rate, both directions, during period of speed measurements (veh/h); and

$f_{HV,ATS}$ = heavy vehicle adjustment factor for ATS, from Equation 15-4 or Equation 15-5.

Estimating FFS

FFS on two-lane highways ranges from 45 mi/h to as high as 70 mi/h. BFFS reflects alignment of the facility and the nature of traffic.

The FFS can be estimated reliably if field data are not available. This is a greater challenge on two-lane highways than on other types of uninterrupted-flow facilities. FFS on two-lane highways covers a significant range, from as low as 45 mi/h to as high as 70 mi/h. To estimate the FFS, the analyst must characterize the operating conditions of the facility in terms of a BFFS that reflects the nature of the traffic and the alignment of the facility. Unfortunately, because of the broad range of speeds that occur and the importance of local and regional factors that influence driver-desired speeds, little guidance on estimating the BFFS can be given.

AR0073728

Estimates of BFFS can be developed on the basis of speed data and local knowledge of operating conditions on similar facilities. As will be seen, once the BFFS is determined, adjustments for lane and shoulder widths and for the density of unsignalized access points are applied to estimate the FFS. In concept, the BFFS is the speed that would be expected on the basis of the facility's horizontal and vertical alignment, if standard lane and shoulder widths were present and there were no roadside access points. Thus, the *design speed* of the facility might be an acceptable estimator of BFFS, since it is based primarily on horizontal and vertical alignment. Posted speed limits may not reflect current conditions or driver desires. A rough estimate of BFFS might be taken as the posted speed limit plus 10 mi/h.

Once a BFFS is determined, the actual FFS may be estimated as follows:

$$FFS = BFFS - f_{LS} - f_A \quad \text{Equation 15-2}$$

where

FFS = free-flow speed (mi/h),

$BFFS$ = base free-flow speed (mi/h),

f_{LS} = adjustment for lane and shoulder width (mi/h), and

f_A = adjustment for access-point density (mi/h).

When field measurements are used to estimate FFS, standard approaches and sampling techniques should be applied. Guidance on field speed studies is provided in standard traffic engineering texts and elsewhere (3).

Adjustment factors for use in Equation 15-2 are found in Exhibit 15-7 (lane and shoulder width) and Exhibit 15-8 (access-point density).

Exhibit 15-7
Adjustment Factor for Lane and Shoulder Width (f_{LS})

Lane Width (ft)	Shoulder Width (ft)			
	≥0 ≤2	>2 ≤4	>4 ≤6	≥6
≥9 <10	6.4	4.8	3.5	2.2
≥10 <11	5.3	3.7	2.4	1.1
≥11 <12	4.7	3.0	1.7	0.4
≥12	4.2	2.6	1.3	0.0

Exhibit 15-8
Adjustment Factor for Access-Point Density (f_A)

Access Points per Mile (Two Directions)	Reduction in FFS (mi/h)
0	0.0
10	2.5
20	5.0
30	7.5
40	10.0

Note: Interpolation to the nearest 0.1 is recommended.

The access-point density is computed by dividing the total number of unsignalized intersections and driveways on both sides of the roadway segment by the length of the segment (in miles). Thus, in analyzing the two directions of the highway and estimating the FFS, the FFS will be the same in both directions. If the FFS is measured in the field, the value could be different in each direction.

If a highway contains sharp horizontal curves with design speeds substantially below those of the rest of the segment, it may be desirable to

AR0073729

determine the PFS separately for curves and tangents and to compute a weighted-average PFS for the segment as a whole.

The data for PFS relationships in this chapter include both commuter and noncommuter traffic. There were no significant differences between the two. However, it is expected that commuters and other regular users will use a facility more efficiently than recreational and other occasional users. If the effect of driver population is a concern, the PFS should be measured in the field.

Step 3: Demand Adjustment for ATS

This computational step is applied only to cases of Class I and Class III two-lane highways. LOS on Class II highways is not based on ATS, and therefore this step is skipped for those highways.

Demand volumes on both directions (analysis direction and opposing direction) must be converted to flow rates under equivalent base conditions with Equation 15-3:

Equation 15-3

$$v_{d,ATS} = \frac{V_d}{PHF \times f_{g,ATS} \times f_{HV,ATS}}$$

where

$v_{d,ATS}$ = demand flow rate for ATS estimation (pc/h),

d = "d" (analysis direction) or "o" (opposing direction),

V_d = demand volume for direction d (veh/h),

$f_{g,ATS}$ = grade adjustment factor, from Exhibit 15-9 or Exhibit 15-10, and

$f_{HV,ATS}$ = heavy vehicle adjustment factor, from Equation 15-4 or Equation 15-5.

PHF

The PHF represents the variation in traffic flow within the hour. Two-lane highway analysis is based on the demand flow rates for a peak 15-min period within the analysis hour—usually (but not necessarily) the peak hour. If flow rates for the peak 15 min have been directly measured, the PHF used in Equation 15-3 is set equal to 1.00.

ATS Grade Adjustment Factor

The grade adjustment factor $f_{g,ATS}$ depends on the terrain. Factors are defined for:

- Extended segments (≥2 mi) of level terrain,
- Extended segments (≥2 mi) of rolling terrain,
- Specific upgrades, and
- Specific downgrades.

Any grade of 3% or steeper and 0.5 mi or longer will be analyzed as a specific upgrade or downgrade, depending on the analysis direction being considered. However, a grade of 3% or more may be analyzed as a specific grade if it is 0.25 mi or longer.

AR0073730

Exhibit 15-9 shows grade adjustment factors for extended segments of level and rolling terrain, as well as for specific downgrades. Exhibit 15-9 is entered with the one-direction demand flow rate $v_{d,i}$, in vehicles per hour.

Exhibit 15-9
ATS Grade Adjustment Factor ($f_{g,ATS}$) for Level Terrain, Rolling Terrain, and Specific Downgrades

One-Direction Demand Flow Rate, $v_{d,i}$ (veh/h)	Adjustment Factor	
	Level Terrain and Specific Downgrades	Rolling Terrain
≤100	1.00	0.77
200	1.00	0.75
300	1.00	0.83
400	1.00	0.90
500	1.00	0.95
600	1.00	0.97
700	1.00	0.98
800	1.00	0.99
≥900	1.00	1.00

Note: Interpolation in the 4-level 0.01's recommended.

If demand is expressed as an hourly volume, it must be divided by the PHF ($v_{d,i} = V/PHF$) to obtain the appropriate factor. Other adjustment factor tables associated with Equation 15-3 are entered with this value as well.

Note that the adjustment factor for level terrain is 1.00, since level terrain is one of the base conditions. For the purposes of grade adjustment, specific downgrade segments are treated as level terrain.

Exhibit 15-10 shows grade adjustment factors for specific upgrades. The negative impact of upgrades on two-lane highway speeds increases as both the severity of the upgrade and its length increase. The impact, however, declines as demand flow rate increases. At higher demand flow rates, lower speeds would already result, and the additional impact of the upgrades is less severe.

ATS Heavy Vehicle Adjustment Factor

The base conditions for two-lane highways include 100% passenger cars in the traffic stream. This is a rare circumstance, and the presence of heavy vehicles in the traffic stream reduces the ATS.

In general, a heavy vehicle is defined as any vehicle (or vehicle-trailer unit) with more than four wheels on the ground during normal operation. Heavy vehicles are classified as trucks or recreational vehicles (RVs). Trucks cover a wide variety of vehicles from small pickup and panel trucks with more than four wheels to double and triple tractor–trailer units. Small pickup and panel trucks with only four wheels are classified as passenger cars. All school, transit, or intercity buses are classified as trucks. The RV classification also covers a wide range of vehicles, including motorized campers, motor homes, and cars or small trucks that are towing trailers.

AR0073731

Exhibit 15-10

	700	1.1	1.6
	800	1.1	1.4
	≥900	1.0	1.3
RVs, E_R	All flows	1.0	1.1

Note: Interpolation to the nearest 0.1 is recommended.

AR0073732

Determining the heavy vehicle adjustment factor is a two-step process:

1. Passenger car equivalents are found for trucks (E_T) and RVs (E_R) under prevailing conditions.
2. A heavy vehicle adjustment factor is computed from the passenger car equivalents with Equation 15-4:

$$f_{HV,ATS} = \frac{1}{1 + P_T(E_T - 1) + P_R(E_R - 1)} \quad \text{Equation 15-4}$$

where

$f_{HV,ATS}$ = heavy vehicle adjustment factor for ATS estimation,

P_T = proportion of trucks in the traffic stream (decimal),

P_R = proportion of RVs in the traffic stream (decimal),

E_T = passenger car equivalent for trucks from Exhibit 15-11 or Exhibit 15-13, and

E_R = passenger car equivalent for RVs from Exhibit 15-11 or Exhibit 15-13.

The passenger car equivalent is the number of passenger cars displaced from the traffic stream by one truck or RV. Passenger car equivalents are defined for several situations.

- Extended sections of general level or rolling terrain,
- Specific upgrades, and
- Specific downgrades.

Exhibit 15-11 contains passenger car equivalents for trucks and RVs in general terrain segments and for specific downgrades, which are treated as level terrain in most cases. A special procedure is provided in the next section to evaluate specific downgrades on which significant numbers of trucks must reduce their speed to crawl speed to maintain control.

Exhibit 15-12 and Exhibit 15-13 show passenger car equivalents for trucks and RVs, respectively, on specific upgrades.

ATS Passenger Car Equivalents for Specific Downgrades Where Trucks Travel at Crawl Speed

As noted previously, any downgrade of 3% or more and 0.6 mi or longer must be analyzed as a specific downgrade. If the slope of the downgrade varies, it should be analyzed as a single composite by using an average grade computed by dividing the total change in elevation by the total length of grade and expressing the result as a percentage.

Most specific downgrades will be treated as level terrain for analysis purposes. Some downgrades, however, are severe enough to force some trucks into crawl speed. In such cases, the truck drivers are forced to operate in a low gear to apply engine braking, since the normal brake system would not be sufficient to slow or stop a heavy vehicle from gaining too much momentum as it travels down a steep downgrade. There are no general guidelines for identifying when or where these situations will occur, other than direct observation of heavy vehicle operations.

AR0073733

AR0073734

When this situation exists, the heavy vehicle adjustment factor $f_{HV,ATS}$ is found with Equation 15-5 instead of Equation 15-4:

$$f_{HV,ATS} = \frac{1}{1 + P_{t,ATS} \times P_T(E_T - 1) + (1 - P_{t,ATS}) \times P_R \times (E_R - 1) + P_B(E_B - 1)}$$

Equation 15-5

where

$P_{t,ATS}$ = proportion of trucks operating at crawl speed (decimal); and

E_T = passenger car equivalent for trucks operating at crawl speed, from Exhibit 15-14.

All other variables are as previously defined. Note that $P_{t,ATS}$ is the flow rate of trucks traveling at crawl speed divided by the flow rate of all trucks.

Exhibit 15-14
ATS Passenger Car Equivalents (E_T) for Trucks on Downgrades Traveling at Crawl Speed

Difference Between FFS and Truck Crawl Speed (mi/h)	Directional Demand Flow Rate, $v_{d,ATS}$ (veh/h)								
	≤100	200	300	400	500	600	700	800	>900
10	4.7	4.1	3.6	3.1	2.5	2.1	1.6	1.3	1.0

40	22.8	20.6	17.5	15.6	13.1	11.6	9.2	6.1	4.2
50	29.8	26.0	23.1	20.3	17.5	14.6	11.9	9.2	6.5
60	35.9	32.2	28.6	24.9	21.9	18.1	14.7	11.3	7.9

Note: Interpolation against both speed difference and demand flow rate to the nearest 0.1 is recommended.

Step 4: Estimate the ATS

As was the case with Step 3, this step applies only to Class I and Class III two-lane highways. Class II highways do not use ATS as a LOS measure.

The ATS is estimated from the FFS, the demand flow rate, the opposing flow rate, and the percentage of no-passing zones in the analysis direction. The ATS is computed from Equation 15-6:

$$ATS_d = FFS - 0.0077(v_{d,ATS} + v_{o,ATS}) \times f_{np,ATS}$$

Equation 15-6

where

ATS_d = average travel speed in the analysis direction (mi/h),

FFS = free-flow speed (mi/h),

$v_{d,ATS}$ = demand flow rate for ATS determination in the analysis direction (pc/h),

$v_{o,ATS}$ = demand flow rate for ATS determination in the opposing direction (pc/h), and

$f_{np,ATS}$ = adjustment factor for ATS determination for the percentage of no-passing zones in the analysis direction, from Exhibit 15-15.

AR0073735

1,400	0.3	0.3	0.5	0.6	0.7
≥1,600	0.3	0.3	0.4	0.4	0.6

Note: Interpolation of $f_{np,ATS}$ for percent no-passing zones, demand flow rate, and FFS to the nearest 1 is recommended.

Exhibit 15-15 is entered with v_o in passenger cars per hour, not v_{op} in vehicles per hour. At this point in the computational process, fully adjusted demand flow rates are available and are used in the determination of ATS. As shown in this exhibit, the effect of no passing zones is greatest when opposing flow rates are low. As opposing flow rates increase, the effect decreases to zero, since passing and no passing zones become irrelevant when the opposing flow rate allows no opportunities to pass.

Step 5: Demand Adjustment for PTSF

This computational step is applied only in cases of Class I and Class II two-lane highways. LOS on Class II highways is not based on PTSF, and therefore this step is skipped for those highways.

AR0073736

The demand volume adjustment process for estimating PTSF is structurally similar to that for ATS. The general approach is the same, but different adjustment factors are used, and the resulting adjusted flow rates will be different from those used in estimating ATS. Therefore, a detailed discussion of the process is not included here, since it is the same as that described for ATS estimates.

Equation 15-7 and Equation 15-8 are used to determine demand flow rates for the estimation of PTSF:

$$v_{i,PTSF} = \frac{V_i}{PHF \times f_{g,PTSF} \times f_{HV,PTSF}} \quad \text{Equation 15-7}$$

$$f_{HV,PTSF} = \frac{1}{1 + P_T(E_T - 1) + P_R(E_R - 1)} \quad \text{Equation 15-8}$$

where

$v_{i,PTSF}$ = demand flow rate i for determination of PTSF (pc/h);

i = "d" (analysis direction) or "o" (opposing direction);

$f_{g,PTSF}$ = grade adjustment factor for PTSF determination, from Exhibit 15-16 or Exhibit 15-17; and

$f_{HV,PTSF}$ = heavy vehicle adjustment factor for PTSF determination, from Exhibit 15-18 or Exhibit 15-19.

All other variables are as previously defined.

PTSF Grade Adjustment Factor

As was the case for the ATS adjustment process, grade adjustment factors are defined for general terrain segments (level or rolling), specific upgrades, and specific downgrades. Exhibit 15-16 gives the adjustment factors for general terrain segments and specific downgrades (which are treated as level terrain). Exhibit 15-17 shows adjustment factors for specific upgrades. These adjustments are used to compute demand flow rates, and the exhibits are again entered with $v_{o,i} \cdot VDH$.

Exhibit 15-16
PTSF Grade Adjustment Factor ($f_{g,PTSF}$) for Level Terrain, Rolling Terrain, and Specific Downgrades

Note: Interpolation for grades of a specific length is recommended.

PTSF Heavy Vehicle Adjustment Factor

The process for determining the heavy vehicle adjustment factor used in estimating PTSF (Equation 15-6) is similar to that used in estimating ATS. Passenger car equivalents must be found for trucks (E_T) and recreational vehicles (E_R). Equivalents for both trucks and RVs in general terrain segments (level, rolling) and on specific downgrades (which are treated as level terrain) are found in Exhibit 15-18. In estimating PTSF, there is no special procedure for trucks traveling at crawl speed on specific downgrades. Equivalents for trucks and RVs on specific upgrades are found in Exhibit 15-19.

Exhibit 15-18
PTSF Passenger Car Equivalents for Trucks (E_T) and RVs (E_R) for Level Terrain, Rolling Terrain, and Specific Downgrades

Note: Interpolation is used to estimate passenger car equivalents for intermediate values of grade length.

Step 6: Estimate the PTSF

This step is only applied to Class I and Class II two-lane highways. Class III highways do not use PTSF to determine LOS.

Once the demand flows for estimating PTSF are computed, the PTSF is estimated with Equation 15-9:

$$PTSF_d = BPTSF_d + f_{np,PTSF}\left(\frac{v_{d,PTSF}}{v_{d,PTSF} + v_{o,PTSF}}\right)^x$$

Equation 15-9

where

$PTSF_d$ = percent time spent following in the analysis direction (decimal);

$BPTSF_d$ = base percent time spent following in the analysis direction, from Equation 15-10;

$f_{np,PTSF}$ = adjustment to PTSF for the percentage of no-passing zones in the analysis segment, from Exhibit 15-25;

$v_{d,PTSF}$ = demand flow rate in the analysis direction for estimation of PTSF (pc/h); and

$v_{o,PTSF}$ = demand flow rate in the opposing direction for estimation of PTSF (pc/h).

The base percent time spent following (BPTSF) applies to base conditions and is estimated by Equation 15-10:

AR0073739

Equation 15-10

$$HPTSF_i = 100\left[1 - \exp\left(av_o^b\right)\right]$$

where a and b are constants drawn from Exhibit 15-20 and all other terms are as previously defined.

Exhibit 15-20 and Exhibit 15-21 are entered with demand flow rates fully converted to passenger cars per hour under base conditions (v_p and v_o).

Exhibit 15-20
PTSF Coefficients for Use in Equation 15-10 for Estimating BPTSF

Opposing Demand Flow Rate, v_o (pc/h)	Coefficient a	Coefficient b
≤200	-0.0014	0.973
400	-0.0022	0.928
600	-0.0033	0.870

2,200	3.5	7.0	8.5	10.1	10.4	10.7
Directional Split = 90/10						
≤200	6.5	24.1	33.6	43.1	43.4	43.8
400	3.0	20.7	29.3	36.9	38.7	37.6
600	-3.1	16.8	23.5	30.1	30.6	31.1
800	-4.8	10.5	15.2	19.9	20.3	20.8
1,400	1.2	5.5	8.3	11.0	11.5	11.9

Note: Straight-line interpolation of $f_{np,pt}$ for percent no-passing zones, demand flow rate, and directional split is recommended to the nearest 0.1.

AR0073740

Note that in Exhibit 15-21, the adjustment factor depends on the total two-way demand flow rate, even though the factor is applied to a single directional analysis. The factor reflects not only the percent of no-passing zones in the analysis segment but also the directional distribution of traffic. The directional distribution assumed is the same regardless of the direction being considered. Thus, for example, splits of 70/30 and 30/70 result in the same factor, all other variables being constant. Equation 15-9, however, adjusts the factor to reflect the balance of flows in the analysis and opposing directions.

Step 7: Estimate the PFFS

This step is included only in the analysis of Class III two-lane highways. PFFS is not used in the determination of LOS for Class I or Class II facilities. The computation is straightforward, since both the FFS and the ATS have already been determined in previous steps. PFFS is estimated from Equation 15-11:

$$PFFS = \frac{ATS_d}{FFS} \qquad \text{Equation 15-11}$$

where all terms are as previously defined.

Step 8: Determine LOS and Capacity

LOS Determination

At this point in the analysis, the values of any needed measure(s) have been determined. The LOS is found by comparing the appropriate measures with the criteria of Exhibit 15-3. The measure(s) used must be appropriate to the class of the facility being studied:

- Class I: ATS and PTSF;
- Class II: PTSF; and
- Class III: PFFS.

For Class I highways, two service measures are applied. When Exhibit 15-3 is entered, therefore, two LOS designations can be obtained. The worse of the two is the prevailing LOS. For example, if ATS results in a LOS C designation and PTSF results in a LOS D designation, LOS D is assigned.

Capacity Determination

Capacity, which exists at the boundary between LOS E and F, is not determined by a measure of effectiveness. Under base conditions, the capacity of a two-lane highway (in one direction) is 1,700 pc/h. To determine the capacity under prevailing conditions, relevant adjustment factors must be applied to Equation 15-3 and Equation 15-7. In this case, however, the demand flow rate of 1,700 pc/h under base conditions is known, and the demand flow rate under prevailing conditions is sought.

First, capacity is defined as a flow rate, so the PHF in Equation 15-3 and Equation 15-7 is set at 1.00. Then, Equation 15-12 or Equation 15-13 (or both) are applied, as described below.

AR0073741

Equation 15-12

$$c_{ATS} = 1{,}700 f_{g,ATS} f_{HV,ATS}$$

Equation 15-13

$$c_{PTSF} = 1{,}700 f_{g,PTSF} f_{HV,PTSF}$$

where

c_{ATS} = capacity in the analysis direction under prevailing conditions based on ATS (pc/h), and

c_{PTSF} = capacity in the analysis direction under prevailing conditions based on PTSF (pc/h).

For Class II highways, both capacities must be computed. The lower value represents capacity. For Class I highways, only the PTSF-based capacity is computed. For Class III highways, only the ATS-based capacity is computed.

One complication is that the adjustment factors depend on the demand flow rate (in vehicles per hour). Thus, adjustment factors for a base flow rate of 1,700 pc/h must be used. Technically, this value should be adjusted to reflect grade and heavy vehicle adjustments. This would create an iterative process in which a result is guessed and then checked.

In practical terms, this is unnecessary, since the highest flow group in all adjustment exhibits is greater than 900 veh/h. It is highly unlikely that any adjustments would reduce 1,700 pc/h to less than 900 veh/h. Therefore, in capacity determinations, all adjustment factors should be based on a flow rate greater than 900 veh/h.

Capacity must be limited by the directional distribution of traffic and the total two-way flow capacity of 3,200 pc/h.

Another characteristic of this methodology must be considered in computing capacity. Where the directional distribution is other than 50/50 (in level and rolling terrain), the two-way capacity implied by such directional capacity may be different. Moreover, the implied two-way capacity from either or both directions may be more than the limit of 3,200 pc/h. In such cases, the directional capacities estimated are not achievable with the stated directional distribution. If this is the case, then base capacity is restricted to 1,700 pc/h in the direction with the heaviest flow, and capacity in the opposing direction is found by using the opposing proportion of flow, with an upper limit of 3,200 pc/h.

Directional Segments with Passing Lanes

Providing a passing lane on a two-lane highway in level or rolling terrain improves operational performance and therefore may improve LOS. A procedure to estimate this effect is described in this section.

This procedure should be applied only in level and rolling terrain. On specific grades, added lanes are considered to be climbing lanes, which are addressed in the next section.

The effective length of a passing lane is longer than its actual length.

Exhibit 15-22 illustrates the operational effect of a passing lane on PTSF. It shows that the passing lane provides operational benefits for some distance downstream before PTSF returns to its former level (without a passing lane). Thus, a passing lane's effective length is greater than its actual length.

Source: Harwood and Hoban [9].

Exhibit 15-22
Operational Effect of a Passing Lane on PTSF

Exhibit 15-23 gives the length of the downstream segment affected by the passing lane for both ATS and PTSF. In the case of ATS, the effect is limited to 1.7 mi in all cases. Where PTSF is concerned, however, the effect can be far longer than the passing lane itself—up to 13 mi for low demand flow rates.

Directional Demand Flow Rate, v_d (pc/h)	Downstream Length of Roadway Affected, L_{ds} (mi)	
	PTSF	ATS
≤200	13.0	1.7
300	11.6	1.7
400	8.1	1.7
500	7.0	1.7
600	6.5	1.7
700	5.7	1.7
800	5.0	1.7
900	4.3	1.7
≥1,000	3.8	1.7

Note: Interpolation to the nearest 0.1 is recommended.

Exhibit 15-23
Downstream Length of Roadway Affected by Passing Lanes on Directional Segments in Level and Rolling Terrain

The procedure here is intended for the analysis of directional segments in level or rolling terrain that encompass the entire passing lane. Segments of the highway upstream and downstream of the passing lane may be included in the analysis. It is recommended that the analysis segment include the full length of the passing lane's downstream effect.

The analysis segment should include the entire length of the passing lane's downstream effect.

Because of the downstream effect on PTSF, the LOS of a two-lane highway segment that is determined by PTSF (Class I and Class II) may be significantly improved by the addition of a passing lane. Care must be taken, however, in considering the impact of a passing lane on service volumes or service flow rates. The result is highly dependent on the relative lengths of the analysis segment and the passing lane. If the analysis segment includes only the length of the passing lane and its downstream effective length (on PTSF), the passing lane may appear to increase service flow rates dramatically at LOS A–D (capacity and therefore LOS E, would not be affected). However, if additional lengths are included in the analysis segment, this impact is reduced, sometimes considerably. Thus, apparent increases in service volumes or service flow rates must be carefully considered in the context of how they were obtained.

Care should be taken in considering the effect of passing lanes on service flow rates. They are greatly affected by the length of the passing lane relative to the length of the analysis segment.

The steps of this special analysis procedure are as follows:

AR0073743

Step 1: Conduct an Analysis Without the Passing Lane

The first step in the operational analyses of the impact of a passing lane is to conduct the basic analysis steps described previously. The remainder of the procedure essentially predicts the improvement caused by the passing lane compared with a similar segment without a passing lane.

Step 2: Divide the Segment into Regions

The analysis segment can be divided into four regions, as follows:

1. Length upstream of the passing lane L_u,
2. Length of the passing lane L_p,
3. Length downstream of the passing lane within its effective length L_d, and
4. Length downstream of the passing lane beyond its effective length L_o.

Some of these regions may not be involved in a particular analysis. Region 2, the passing lane, must be included in every analysis. In addition, it is strongly recommended, but not absolutely necessary, that Region 3 be included. Regions 1 and 4 are optional, and inclusion is at the discretion of the analyst.

The four lengths must add up to the total length of the analysis segment. The analysis regions and their lengths will differ for estimations of ATS and PTSF, as the downstream effects indicated in Exhibit 15-23 differ for each.

The length of the passing lane L_p is either the length of the passing lane as constructed or the planned length. It should include the length of the lane addition as well as the length of the entrance and exit tapers. The procedure is calibrated for passing lanes within the optimal lengths shown in Exhibit 15-24. Passing lanes that are substantially shorter or longer than the optimums shown may provide less operational benefit than predicted by this procedure.

Exhibit 15-24
Optimal Lengths of Passing Lanes on Two-Lane Highways

Directional Demand Flow Rate, v_d (pc/h)	Optimal Passing Lane Length (mi)
≤100	≥0.50
>100 ≤400	>0.50 ≤0.75
>400 ≤700	>0.75 ≤1.00
>700	>1.00 <2.00

The length of the conventional two-lane highway segment upstream of the passing lane L_u is determined by the actual or planned placement of the passing lane within the analysis segment. The length of the downstream highway segment within the effective length of the passing lane L_d is determined from Exhibit 15-23. Any remaining length of the analysis segment downstream of the passing lane is included in L_o, which is computed from Equation 15-14:

Equation 15-14

$$L_o = L_t - (L_u + L_p + L_d)$$

where L_t is the total length of the analysis segment in miles and all other terms are as previously defined.

Step 3: Determine the PTSF

PTSF within lengths L_u and L_d is assumed to be equal to the $PTSF_d$ as predicted by the normal analysis procedure (without a passing lane). Within the segment with the passing lane, L_p, PTSF is generally equal to 55% to 62% of its

AR0073744

upstream value. This effect is a function of the directional demand flow rate. Within L_d, the PTSF is assumed to increase linearly from the passing lane value to the normal upstream value. This distribution is illustrated in Exhibit 15-25.

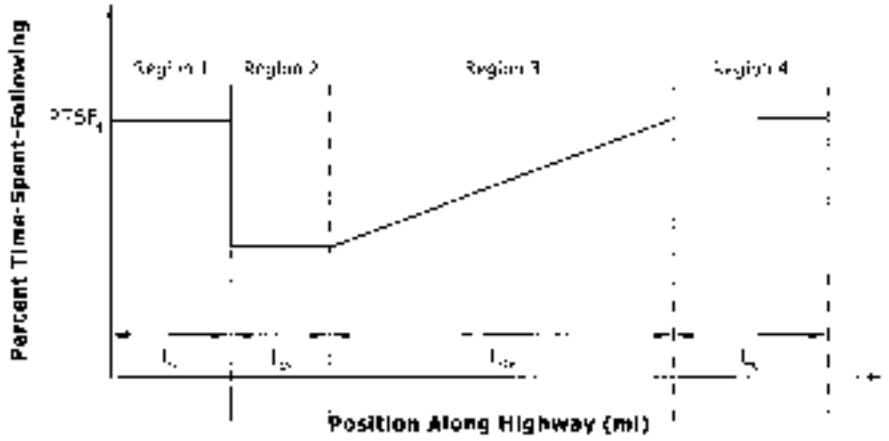

Exhibit 15-25
Effect of a Passing Lane on PTSF

On the basis of this model, the PTSF for the entire analysis segment, as affected by the passing lane, is given by Equation 15-15:

$$PTSF_{pl} = \frac{PTSF_1 \left[L_u + L_d + f_{pl,PTSF} L_{d2} \left(\frac{1 + f_{pl,PTSF}}{2} \right) \right]}{L_r} \quad \text{Equation 15-15}$$

where

$PTSF_{pl}$ = percent time spent-following for segment as affected by the presence of a passing lane (decimal); and

$f_{pl,PTSF}$ = adjustment factor for the impact of a passing lane on percent time spent following, from Exhibit 15-26.

All other variables are as previously defined.

Directional Demand Flow Rate, v_d (pc/h)	$f_{pl,PTSF}$
≤100	0.58
200	0.59
300	0.60
400	0.61
500	0.61
600	0.61
700	0.62
800	0.62
≥900	0.62

Note: Interpolation is not recommended; use next value.

Exhibit 15-26
Adjustment Factor for the Impact of a Passing Lane on PTSF ($f_{pl,PTSF}$)

If the analysis segment cannot encompass the entire length L_d because it is truncated by a town or major intersection within it, then distance L_r is not used. Therefore, the actual downstream length within the analysis segment, L_d, is less than the value of L_d tabulated in Exhibit 15-23. In this case, Equation 15-16 should be used instead of Equation 15-15:

AR0073745

Equation 15-16

$$PTSF_d = \frac{PTSF_u L_u + f_{pe,ms} L_d + f_{pe,ms} L_{ds} \left[\left(1 - f_{pe,ms} \right) \left(\frac{L_d}{L_{ds}} \right) \right]}{L_t}$$

where all terms are as previously defined.

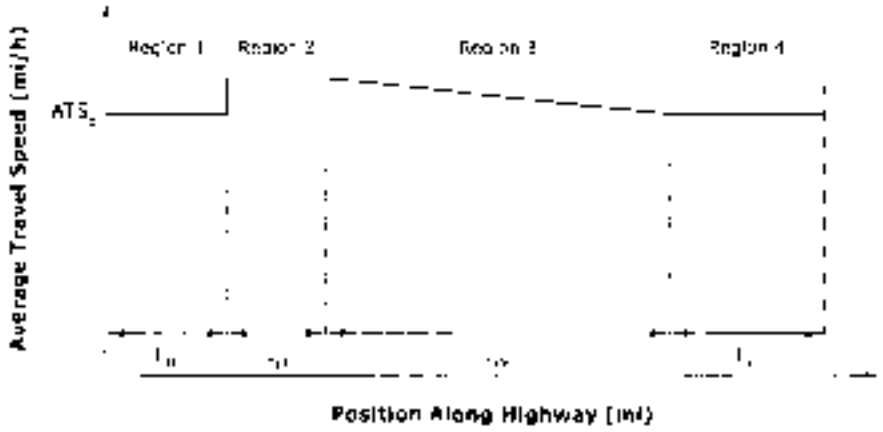
In general, the effective downstream distance of the passing lane should not be truncated. A downstream boundary short of the effective downstream distance should be considered at the point where any of the following occur:

- The environment of the highway radically changes, as in the case of entering a small town or developed area from a rural segment;
- A major unsignalized intersection is present, leading to a change in the demand flow rate;
- A proximate signalized intersection begins to affect the operation of the two-lane segment;
- The terrain changes significantly; and
- Lane or shoulder widths change significantly.

Step 4: Determine the ATS

The ATS within lengths L_u and L_d is assumed to be equal to ATS_o, the speed that would exist without the passing lane. Within the passing lane, the ATS is generally between 5% and 15% higher than its upstream value, depending on the directional demand flow rate. Within the effective downstream length, L_{ds}, ATS is assumed to decrease linearly with the distance from the passing lane, from the passing lane value to the normal value. Exhibit 15-27 illustrates the impact of a passing lane on ATS.

Exhibit 15-27
Impact of a Passing Lane on ATS



The ATS is computed with Equation 15-17.

Equation 15-17

$$ATS_d = \frac{ATS_o L_t}{L_u + L_d + \left(\frac{f_{pe,ATS}}{f_{pe,ATS}} \right) \left(\frac{2L_{ds}}{1 + f_{pe,ATS}} \right)}$$

AR0073746

where

ATS_d = average travel speed in the analysis segment as affected by a passing lane (mi/h), and

$f_{pl,ATS}$ = adjustment factor for the effect of a passing lane on ATS, from Exhibit 15-28.

All other variables are as previously defined.

Directional Demand Flow Rate, v_d (pc/h)	$f_{pl,ATS}$
≤100	1.00
200	1.00
300	1.00
400	1.00
500	1.00
600	1.01
700	1.01
800	1.01
≥900	1.01

Note: Interpolation is not recommended; use nearest value.

Exhibit 15-28
Adjustment Factor for Estimating the Impact of a Passing Lane on ATS ($f_{pl,ATS}$)

In the case where the analysis segment cannot include all of the effective downstream distance, L_{ds}, because a town or major intersections cause the segment to be truncated, a value of L_d is less than the value of L_{ds}. In this case, Equation 15-38 is used instead of Equation 15-37 to compute ATS.

$$ATS_d = \frac{1}{\frac{L_d}{ATS_f + f_{pl,ATS}} + \left[1 - f_{pl,ATS} + \left(f_{pl,ATS} - 1\right)\left(\frac{L_{ds} - L_d}{L_{ds}}\right)\right]\frac{2.0}{ATS_f}}$$

Equation 15-38

where all terms are as previously defined.

Step 5: Determine the LOS

Determining the LOS for a segment with a passing lane is no different from determining the LOS for a normal segment, except that ATS_d and $PTSF_d$ are used as the service measures with the criteria of Exhibit 15-3.

As with a normal segment, LOS for Class I highways is based on both PTSF and ATS. LOS for Class II highways is based only on PTSF. Class III highways would not normally have passing lanes, but if such a situation arose, PFFS or AFSLOS would be used to determine LOS.

Directional Segments with Climbing Lanes on Upgrades

A climbing lane is, in effect, a passing lane added on an upgrade to allow traffic to pass heavy vehicles whose speeds are reduced. Generally, a lane is added to the right, and all slower-moving vehicles should move to this lane, allowing faster vehicles to pass in the normal lane.

The American Association of State Highway and Transportation Officials (7) indicates that climbing lanes on two-lane highways are warranted when

- The directional flow rate on the upgrade exceeds 200 veh/h,
- The directional flow rate for trucks on the upgrade exceeds 20 veh/h, and

AR0073747

- Any of the following conditions apply:
  - A speed reduction of 10 mi/h or more exists for a typical truck,
  - LOS E or F exists on the upgrade without a climbing lane, or
  - Without a climbing lane, the LOS is two or more levels lower on the upgrade than on the approach segment to the grade.

An operational analysis of the impact of a climbing lane on a two-lane highway is performed with the same procedures as passing lanes in level or rolling terrain, with three major differences:

1. Adjustment factors for the existence of the climbing lane are taken from Exhibit 15-29,
2. The analysis without a climbing lane is conducted by using the specific grade procedures, and
3. Distances L_d and L_u are set to zero.

The effective downstream distance L_d is also generally set to zero unless the climbing lane ends before the grade does. In this case, a value less than the values typically used should be considered.

Exhibit 15-29
Adjustment Factors (f_G) for Estimating ATS and PTSF Within a Climbing Lane

Directional Demand Flow Rate, v_i (pc/h)	f_G	
	ATS	PTSF
0–420	1.02	0.20
>300–600	1.07	0.21
>600	1.14	0.22

LOS Assessment for Directional Two-Lane Facilities

Two-lane highway segments have uniform characteristics that provide a basis for their analysis. Several contiguous two-lane highway segments (in the same direction) may be combined to look at a longer section (with varying characteristics) as a facility. A separate operational analysis would have to be done for each uniform segment within the facility.

Weighted-average values of PTSF and ATS may be estimated for the facility. The weighting is on the basis of total travel time within the 15-min analysis period. The total travel time of all vehicles within the 15-min analysis period is estimated with Equation 15-19 and Equation 15-20.

Equation 15-19

$$VMT_{15} = 0.25\left(\frac{V_i}{PHF}\right)L_t$$

Equation 15-20

$$DT_i = \frac{VMT_{15i}}{ATS_i}$$

where

VMT_{15i} = total vehicle-miles traveled by all vehicles in directional segment i during the 15-min analysis period (veh-mi),

V_i = demand volume on directional segment i (veh/h),

PHF = peak hour factor,

L_t = total length of directional segment i (mi),

AR0073748

TT_{di} = total travel time consumed by all vehicles traversing directional segment i during the 15-min analysis period (veh-h), and

ATS_i = average travel speed for directional segment i (mi/h).

Once the total travel time for all vehicles in each segment is computed, weighted-average values of PTSF and ATS can be obtained with Equation 15-21 and Equation 15-22:

$$ATS_f = \frac{VMT_1 + VMT_2 + VMT_3 + \ldots + VMT_i}{TT_1 + TT_2 + TT_3 + \ldots + TT_i} \quad \text{Equation 15-21}$$

$$PTSF_f = \frac{(TT_1 \times PTSF_1) + (TT_2 \times PTSF_2) + (TT_3 \times PTSF_3) + \ldots + (TT_i \times PTSF_i)}{TT_1 + TT_2 + TT_3 + \ldots + TT_i} \quad \text{Equation 15-22}$$

where

ATS_f = average travel speed for the facility (mi/h),

$PTSF_f$ = percent time-spent-following for the facility (decimal),

$PTSF_i$ = percent time-spent-following for segment i (decimal),

VMT_i = vehicle miles traveled for segment i (veh-mi), and

TT_i = total travel time of all vehicles in segment i (veh-h).

When a facility is put together, two-lane highway segments of different classes should not be combined. Levels of service for the facility are still based on the criteria of Exhibit 15-3. Class III two-lane highways generally only exist as short segments and would not be expected to cover a distance long enough to form a facility.

Other Performance Measures

This chapter provides detailed methodologies for estimating three measures of effectiveness that are used (depending on the highway class) to determine LOS:

- ATS (mi/h, Class I and Class III highways),
- PTSF (decimal, Class I and Class II highways), and
- PFFS (decimal, Class II highways).

In the previous section, two additional measures were introduced that can be considered as performance measures, even though they are not used to determine LOS. Equation 15-19 and Equation 15-20 can be used to estimate

- Total vehicle miles traveled by all vehicles in the analysis segment during the 15-min analysis period VMT_{15} (veh-mi), and
- Total travel time consumed by all vehicles traversing the analysis segment during the 15-min analysis period TT_{15} (veh-h).

These values may also be of interest in fully understanding the operational quality of the study segment.

A volume-to-capacity (v/c) ratio is also a common performance measure of interest in LOS and capacity analysis. It is most easily computed for two-lane highways with Equation 15-23:

AR0073749

Equation 15-23

$$v/c = \frac{v_d}{1{,}700}$$

where v_d is the directional demand flow rate, converted to equivalent base conditions.

The difficulty in this is that there may be two values of v_d to use for estimating ATS and another for estimating PTSF (depending on the class of highway). For Class I highways, where both measures are used, the result yielding the highest v/c ratio would be used. For Class II highways, only PTSF is used, and only one value would exist. For Class III highways, only ATS is used, and only one value would exist.

BICYCLE MODE

The calculation of bicycle LOS on multilane and two-lane highways shares the same methodology, since multilane and two-lane highways operate in fundamentally the same manner for bicyclists. Cyclists travel much more slowly than the prevailing traffic flow, staying as far to the right as possible and using paved shoulders when available, indicating the need for only one model.

The bicycle LOS model for two-lane and multilane highways uses a travel-time perception model calibrated by using a linear regression (9). The model fits independent variables associated with roadway characteristics to the results of a user survey that rated the comfort of various bicycle facilities. The resulting bicycle LOS score generally ranges from 0.5 to 6.5 and is stratified to produce a LOS A–F result, on the basis of Exhibit 15-4.

Step 1: Gather Input Data

The methodology requires gathering the following input data for the facility in question:

1. Lane width (ft),
2. Shoulder width (ft),
3. Hourly directional motorized vehicle volume (veh/h),
4. Number of directional through lanes (needed for multilane highways),
5. Percentage of heavy vehicles (decimal),
6. Posted speed limit (mi/h),
7. Percentage of segment with occupied on-highway parking (decimal), and
8. Pavement rating.

Pavement rating is determined by using FHWA's 5-point present serviceability rating scale (0–1 [very poor], 2 [poor], 3 [fair], 4 [good], and 5 [very good]). Where data for specific variables are not available, default values may be used as shown in Exhibit 15-5.

Step 2: Calculate the Directional Flow Rate in the Outside Lane

On the basis of the hourly directional volume, the peak hour factor, and the number of directional lanes (one for basic two-lane highways, two or more for

AR0073750

passing lanes on multilane highways), calculate the directional demand flow rate of motorized traffic in the outside lane with Equation 15-24.

$$v_o = \frac{V}{PHF \times N} \quad \text{Equation 15-24}$$

where

v_o = directional demand flow rate in the outside lane (veh/h),

V = hourly directional volume (veh/h),

PHF = peak hour factor, and

N = number of directional lanes (=1 for two-lane highways).

Step 3: Calculate the Effective Width

The effective width of the outside through lane depends on both the actual width of the outside through lane and the shoulder width, since cyclists will be able to travel in the shoulder where one is provided. Moreover, striped shoulders of 4 ft or greater provide more security to cyclists by giving cyclists a clear and place to ride outside of the motorized vehicle travelway. Thus, an 11-ft lane and adjacent 5-ft paved shoulder results in a larger effective width for cyclists than a 16-ft lane with no adjacent shoulder.

Parking occasionally exists along two-lane highways, particularly in developed areas (Class III highways) and near entrances to recreational areas (Class I and Class II highways) where a fee is charged for off-highway parking or where the off-highway parking is inadequate for the parking demand. On-highway parking reduces the effective width, because parked vehicles take up shoulder space and bicyclists leave some shy distance between themselves and the parked cars.

Equation 15-25 through Equation 15-29 are used to calculate the effective width, W_e, on the basis of the paved shoulder width, W_s, and the hourly directional volume, V.

If W_s is greater than or equal to 6 ft,

$$W_e = W_t + W_s - (\%OHP \times 10\text{ ft}) \quad \text{Equation 15-25}$$

If W_s is greater than or equal to 4 ft and less than 6 ft

$$W_e = W_t + W_s - 2 \times (\%OHP(2\text{ ft} - W_s)) \quad \text{Equation 15-26}$$

If W_s is less than 4 ft,

$$W_e = W_t + (\%OHP(2\text{ ft} - W_s)) \quad \text{Equation 15-27}$$

with, if V is greater than 100 veh/h:

$$W_t = W_{LT} - W_s \quad \text{Equation 15-28}$$

Otherwise,

$$W_t = (W_{LT} + W_s) \times (2 - 0.005V) \quad \text{Equation 15-29}$$

where

W_e = effective width as a function of traffic volume (ft).

AR0073751

W_v = outside lane width (ft),

W_s = paved shoulder width (ft),

V = hourly directional volume (veh/h),

W_f = average effective width of the outside through lane (ft), and

P_{OSPF} = percentage of segment with occupied on-highway parking (decimal).

Step 4: Calculate the Effective Speed Factor

The effect of motor vehicle speed on bicycle quality of service is primarily related to the differential between motor vehicle and bicycle travel speeds. For instance, a typical cyclist may travel in the range of 15 mi/h. An increase in motor vehicle speeds from 20 to 25 mi/h is more readily perceived than a speed increase from 60 to 65 mi/h, since the speed differential increases by 33% in the first instance compared with only 11% in the latter. Equation 15-30 shows the calculation of the effective speed factor that accounts for this diminishing effect.

Equation 15-30

$$S_f = 1.1199 \ln(S_R - 20) + 0.8103$$

where

S_f = effective speed factor, and

S_R = posted speed limit (mi/h).

Step 5: Determine the LOS

With the results of Steps 1–4, the bicycle LOS score can be calculated from Equation 15-31:

Equation 15-31

$$BLOS = 0.507 \ln(v_{15}) + 0.199 SF_f (1 + 10.38 HV)^2 - 7.066 (1/P)^2 - 0.005 (W_e)^2 + 0.957$$

where

$BLOS$ = bicycle level of service score,

v_{15} = directional demand flow rate in the outside lane (veh/h),

HV = percentage of heavy vehicles (decimal); if $V < 200$ veh/h, then HV should be limited to a maximum of 50%,

P = FHWA's 5-point pavement surface condition rating, and

W_e = average effective width of the outside through lane (ft).

Finally, the BLOS score value is used in Exhibit 15-6 to determine the bicycle LOS for the segment.

AR0073752

3. APPLICATIONS

This chapter provides methodologies for the analysis of two-lane highway uninterrupted flow segments that serve a wide variety of travel purposes. The procedures are most easily applied in the operational analysis mode to determine the capacity and LOS of a two-lane highway segment with known characteristics. Other applications are also possible.

DEFAULT VALUES

A detailed report on the use of default values in uninterrupted flow analyses, including the analysis of two-lane highways, is given elsewhere (*1*). Specific default values for use with the methodology of this chapter were given in Exhibit 15-5. Default values may also be based on local estimates developed from past observations of a specific site or similar sites in a given jurisdiction.

For operational analysis and design analysis, the use of default values should be minimized wherever possible. Every default value used to replace a field-measured or other site-specific value introduces additional uncertainty into the estimation process and into the accuracy of results. Nevertheless, where no site-specific values are available, default values allow at least an approximate analysis of the situation. For planning and preliminary design analyses, use of default values is generally required, since few details are available at this stage of consideration.

TYPES OF ANALYSIS

Operational Analysis

All geometric, development, and traffic demand characteristics are provided. The LOS that is expected to exist during the analysis period is estimated. A number of alternative performance measures may also be estimated. The methodology of this chapter is most easily used in this mode.

Design Analysis

In design analysis, demand characteristics are generally known. The analysis is intended to give insights into design parameters needed to provide a target LOS for the demand characteristics as stated. For two-lane highways, design decisions are relatively limited. Lane and shoulder widths have a moderate impact on operations but generally do not result in a markedly different LOS.

Typical design projects include horizontal or vertical curve realignments, which may affect percent no-passing zones and free-flow speeds.

The special procedures outlined in this chapter to consider the impacts of passing lanes and climbing lanes can be used to provide critical design insight. However, the comparisons are performed in the operational analysis mode, leading to a comparison of operations with or without the passing or climbing lane.

AR0073753

This chapter's appendix deals with some special design issues related to two-lane highways. However, there is no methodology at this point for estimating the impact of these design treatments on operating quality.

Given the relatively few design parameters involved in a two-lane highway, most design analysis is conducted as an iterative series of operational analyses.

Planning and Preliminary Engineering Analysis

Planning and preliminary engineering analysis has the same objectives as design analysis, except that it occurs early in the process when few details of demand and other characteristics are known. Thus, design analysis is augmented by the use of default values for many inputs.

The other principal characteristic of planning and preliminary engineering analysis is that demands are generally described in terms of two-way AADT.

This chapter includes generalized daily service volume tables covering a specific range of default values. They can be used for a coarse and general evaluation of the likely LOS for a two-lane highway in various settings under an assumed AADT demand. These tables are useful only for the most preliminary of analyses. For example, all two-lane highway segments in a particular region can be considered by using these criteria. Any segments that appear to be operating at an undesirable LOS should be subjected to site-specific study with a more detailed operational analysis before any major design, reconstruction, or investment decisions are made.

SERVICE FLOW RATES, SERVICE VOLUMES, AND DAILY SERVICE VOLUMES

Service flow rates, service volumes, and daily service volumes are useful concepts that can be used in the analysis of many types of facilities, including two-lane highways. The three terms must be clearly understood, because they are very different:

1. Service flow rates (SF_i) represent the maximum directional rate of flow that can be accommodated by a segment while maintaining the designated LOS i.
2. Service volumes (SV_i) represent the maximum directional hourly volume that can be accommodated by a segment while maintaining the designated LOS i during the worst 15-min period of the hour.
3. Daily service volumes (DSV_i) represent the maximum AADT that can be accommodated by a segment while maintaining the designated LOS i during the worst 15 min of the peak hour of the day, in the higher-flow direction.

In general, service flow rates and service volumes are directional values, while the daily service volume is usually stated as total traffic in both directions (since that is how AADT is stated).

The service flow rate for a particular LOS is estimated by using the methodology for the segment type under study (two-lane highways in this

AR0073754

chapter). Equation 15-32 is then used to estimate service volume for a segment, and Equation 15-33 is used to estimate daily service volume for a segment.

$$SV_i = SF_i \times PHF$$ Equation 15-32

$$DSV = \frac{SV_i}{K \times D}$$ Equation 15-33

where K is the proportion of traffic occurring in the peak hour for the study segment and D is the proportion of traffic occurring in the peak direction for the study segment.

For two-lane highways, several complications arise. While all analyses on two-lane highways are for one direction, the two directions interact. Thus, if a two-way daily service volume is estimated by using the service flow rate in one direction, and then again in the other direction, different results could easily be obtained.

As with all uninterrupted-flow segments, capacity is synonymous with the service flow rate for LOS E. Thus, Equation 15-12 and Equation 15-13, presented earlier, may be used to estimate service flow rates for LOS E. Even in this case, there are two equations, since the value will depend on whether ATS or PTSF is the determining LOS parameter.

For other levels of service, the process of determining a service flow rate is more complicated. It would be beneficial if the methodology of this chapter could be used in reverse—that is, start with a value of ATS or PTSF and work backwards to the demand flow rate that would create that value. Unfortunately, virtually all of the adjustment factors used in this process depend on the demand flow rate, which is what the analyst would be trying to find. Such computations would, therefore, be iterative. Finding appropriate service flow rates for each LOS requires an iterative process in which different flow rates are incrementally used until the threshold for a particular LOS is found.

Once service flow rates are found, Equation 15-32 and Equation 15-33 can be used to infer service volumes and daily service volumes.

GENERALIZED DAILY SERVICE VOLUMES

Exhibit 15-30 shows generalized daily service volumes for use in planning and preliminary design. The exhibit provides daily service volume values for three types of segments: (a) a Class I highway in level terrain, (b) a Class I highway in rolling terrain, and (c) a Class II highway in rolling terrain.

Typical conditions assumed for each are given below the table. Various values of K- and D-factors are given. Since these values vary greatly from region to region, the analyst must select the values most appropriate to the particular application. Interpolation may be used, if desired, to obtain intermediate values.

AR0073755

Exhibit 15-30
Generalized Daily Service Volumes for Two-Lane Highways

The Class I—level example assumes higher speeds, with significant passing opportunities.

The Class I—rolling example assumes lower roadside speeds and restricted passing opportunities because of the terrain.

The Class II—rolling example is similar to a series of recreational highways with lower speeds and limited passing opportunities.

K-Factor	D-Factor	Class I—Level LOS B	LOS C	LOS D	LOS E	Class I—Rolling LOS B	LOS C	LOS D	LOS E	Class II—Rolling LOS B	LOS C	LOS D	LOS E
0.09	50%	5.5	9.3	16.5	31.7	4.7	8.4	15.7	30.1	5.0	9.5	16.2	31.7
	55%	4.9	8.7	14.9	30.2	3.7	7.9	14.0	29.2	4.1	8.7	15.0	30.2

	65%	2.6	4.8	8.2	16.4	2.1	3.8	7.3	15.9	2.1	4.8	8.5	16.4

Notes: Volumes are thousands of vehicles per day.
Assumed values for all entries: 12% trucks, PHF = 0.88, 12.0 grades, 0% recreational vehicles, 0 access points/mi.
Assumed values for Class I—level: BFFS = 65 mi/h, 20% no passing zones.
Assumed values for Class I—rolling: BFFS = 60 mi/h, 40% no passing zones.
Assumed values for Class II—rolling: BFFS = 55 mi/h, 60% no passing zones.

A number of interesting characteristics are displayed in Exhibit 15-30:

1. LOS A is not shown. Even in level terrain, it is possible to achieve this level only at very low demand flow rates (almost always lower than 50 veh/h, directional).
2. The range of demand flows falling within LOS E is broad compared with other levels of service. This is because the quality of service on two-lane highways tends to become unacceptable at relatively low v/c ratios. Few two-lane highways are observed operating at or near capacity (except on short segments), because most will have been expanded before capacity demand flows develop.

Exhibit 15-30 should be used only in generalized planning and preliminary engineering analysis. It is best used to examine a number of two-lane highways within a given jurisdiction to determine which need closer scrutiny. If anticipated AADTs on a given segment or facility appear to put the segment or facility into an undesirable LOS, then more site-specific data should be obtained (or forecast) and a full operational analysis conducted before any firm commitments to reconstruct or improve the highway are made.

USE OF ALTERNATIVE TOOLS

No alternative deterministic tools are in common use for two-lane highway analysis. Two-lane highway simulation tools are in various stages of development, but user experience with these tools is insufficient to support the formulation of useful guidance for their application to extend the scope of the procedures described in this chapter.

One of the potentially useful features of two-lane highway simulation is the ability to model specific configurations of a series of no-passing zones, exclusive passing lanes, and access points, all of which are now described in general terms (e.g., percent no-passing zones) in this chapter. Network simulation tools can also use site-specific control devices at specific points.

AR0073756

It is possible to obtain additional performance measures from simulation results. One example is *follower density*, which is defined in terms of the number of followers per mile per lane. This concept, which is discussed in more detail in Chapter 24, Concepts Supplemental, has attracted increasing international interest. Some examples that illustrate potential uses of two-lane highway simulation are presented elsewhere (9).

AR0073757

4. EXAMPLE PROBLEMS

Exhibit 15-31
List of Example Problems

Problem Number	Description	Type of Analysis
1	Find the LOS of a Class I highway in rolling terrain	Operational analysis
2	Find the LOS of a Class II highway in rolling terrain	Operational analysis
3	Find the LOS of a Class III highway in level terrain	Operational analysis
4	Find the LOS of a Class I highway with a passing lane	Operational analysis
5	Find the future service LOS of a four-lane highway	Planning analysis

EXAMPLE PROBLEM 1: CLASS I HIGHWAY LOS

The Facts

A segment of Class I two-lane highway has the following known characteristics:

- Demand volume = 1,600 pc/h (total in both directions)
- Directional split (during analysis period) = 50/50
- PHF = 0.95
- 50% no-passing zones in the analysis segment (both directions)
- Rolling terrain
- 14% trucks, 4% RVs
- 11-ft lane widths
- 4-ft usable shoulders
- 20 access points/mi
- 60-mi/h BFFS
- 10-mi segment length

Find the expected LOS in each direction on the two-lane highway segment as described.

Comments

The problem statement calls for finding the LOS in each direction on a segment in rolling terrain. Because the directional split is 50/50, the solution in one direction will be the same as the solution in the other direction, so only one operational analysis needs to be conducted. The result will apply equally to each direction.

Because this is a Class I highway, both ATS and PTSF must be estimated to determine the expected LOS.

Step 1: Input Data

All input data were specified above.

Step 2: Estimate the FFS

FFS is estimated with Equation 15-2 and adjustment factors found in Exhibit 15-7 (for lane and shoulder width) and Exhibit 15-8 (for access points in both directions). For 12-ft lane widths and 4-ft usable shoulders, the adjustment factor

AR0073758

for these features f_g is 1.7 mi/h for 20 access points/mi, the adjustment factor f_A is 5.0 mi/h. Then:

$$FFS = BFFS - f_g - f_A$$

$$FFS = 60.0 - 1.7 - 5.0 = 53.3 \text{ mi/h}$$

Step 3: Demand Adjustment for ATS

The demand volume must be adjusted to a flow rate in passenger cars per hour under equivalent base conditions. This is accomplished with Equation 15-3:

$$v_{i,ATS} = \frac{V}{PHF \times f_{g,ATS} \times f_{HV,ATS}}$$

Since the demand split is 50/50, both the analysis direction and opposing demand volumes are 1,600/2 = 800 veh/h.

The grade adjustment factor $f_{g,ATS}$ is selected from Exhibit 15-9 for rolling terrain. The table is entered with a demand flow rate $v_{d,i}$ in vehicles per hour, or 800/0.95 = 842 veh/h. By interpolation in Exhibit 15-9 between 800 and 900 veh/h, the factor is 0.99 to the nearest 0.01.

The passenger-car equivalent for trucks and RVs is obtained from Exhibit 15-11, again for a demand flow rate of 842 veh/h. Again, by interpolation between 800 and 900 veh/h, the values obtained are $E_T = 1.4$ and $E_R = 1.1$. The heavy vehicle adjustment is then computed with Equation 15-4:

$$f_{HV,ATS} = \frac{1}{1 + P_T(E_T - 1) + P_R(E_R - 1)}$$

$$f_{HV,ATS} = \frac{1}{1 + 0.14(1.4 - 1) + 0.04(1.1 - 1)}$$

$$f_{HV,ATS} = 0.943$$

Then:

$$v_{i,ATS} = v_{i,ATS} = \frac{800}{0.95 \times 0.99 \times 0.943} = 902 \text{ pc/h}$$

Step 4: Estimate ATS

The ATS is estimated with Equation 15-6. The adjustment factor $I_{np,ATS}$ is found in Exhibit 15-13 for an FFS of 53.3 mi/h, 50% no-passing zones, and an opposing demand flow of 902 veh/h. This selection must use interpolation on all three scales. Note that interpolation is only to the nearest 0.1 for this adjustment factor. Exhibit 15-32 illustrates the interpolation.

AR0073759

Exhibit 15-32
Interpolation for ATS Adjustment Factor

v_o (veh/h)	Factor for FFS = 55 mi/h			Factor for FFS = 50 mi/h		
	40% NPZ	50% NPZ	60% NPZ	40% NPZ	50% NPZ	60% NPZ
800	0.7	0.9	1.1	0.6	0.75	0.9
900		0.8			0.65	
1,000	0.6	0.7	0.8	0.4	0.55	0.7

Notes: $f_{g,ATS}$ = 0.65 + [(0.8 − 0.65)/(3.3 / 5.0)] × 0.749 = 0.7.
NPZ = no passing zone.

Then, Equation 15-6 gives the following:

$$ATS = FFS - 0.00776(v_o + v_o) \times f_{np,ATS}$$

$$ATS = 53.3 - 0.00776(902 + 902) \times 0.7$$

$$ATS = 53.3 - 14.0 \times 0.7 = 38.6 \text{ mi/h}$$

Step 5: Demand Adjustment for PTSF

The adjusted demand used to estimate PTSF is found with Equation 15-7 and Equation 15-8. The grade adjustment factor is taken from Exhibit 15-16 for rolling terrain and a demand flow rate of 800/0.95 = 842 pc/h. Passenger car equivalents for trucks and RVs are taken from Exhibit 15-18. In both exhibits, the demand flow rate of 842 pc/h is interpolated between 800 pc/h and 900 pc/h to obtain the correct values. The following values are obtained.

E_T = 1.00

E_R = 1.0

E_B = 1.0

Then, use of Equation 15-8 gives the following.

$$f_{HV,ATS} = \frac{1}{1 + P_T(E_T - 1) + P_R(E_R - 1)}$$

$$f_{HV,ATS} = \frac{1}{1 + 0.14(1.0 - 1) + 0.04(1.0 - 1)} = 1.00$$

Equation 15-7 gives

$$v_{d,ATS} = \frac{V_o}{PHF \times f_{g,ATS} \times f_{HV,ATS}}$$

$$v_{d,ATS} = v_{p,ATS} = \frac{800}{0.95 \times 1.00 \times 1.00} = 842 \text{ pc/h}$$

Step 6: Estimate PTSF

PTSF is estimated with Equation 15-9 and Equation 15-10. Exhibit 15-20 is used to obtain exponents a and b for Equation 15-10, and Exhibit 15-21 is used to obtain the no-passing-zone adjustment for Equation 15-9. All three require interpolation.

Exponents a and b are based on the opposing flow rate of 842 pc/h, which is interpolated between tabulated values of 800 pc/h and 1,000 pc/h. This is illustrated in Exhibit 15-33.

AR0073760

Opposing Flow Rate (pc/h)	a	b
800	-0.0045	0.833
842	**-0.0046**	**0.832**
1,200	0.0049	0.829

Exhibit 15-33
Interpolation for Exponents *a* and *b* for Equation 15-10

Then, use of Equation 15-10 gives

$$BPTSF = 100\left[1 - \exp\left(ax_3^b\right)\right]$$

$$BPTSF = 100\left[1 - \exp\left(-0.0046 \times 842^{0.832}\right)\right]$$

$$BPTSF = 71.3\%$$

The adjustment factor for no-passing zones must also be interpolated in two variables. Exhibit 15-21 is entered with 50% no-passing zones, a 50/50 directional split of traffic, and a total two-way demand flow rate of 842 + 842 = 1,684 pc/h. The interpolation is illustrated in Exhibit 15-34.

Total Flow Rate (pc/h)	Adjustment Factor for 40% NPZ	Adjustment Factor for 50% NPZ	Adjustment Factor for 60% NPZ
1,400	23.8	*25.0*	26.2
1,684		16.6 + (25.0 - 16.6) (136 / 600) = **21.0**	
2,000	15.0	*16.5*	17.4

Note: NPZ = no-passing zone.

Exhibit 15-34
Interpolation for $f_{np,ATS}$ for Equation 15-9

Then, use of Equation 15-9 gives

$$PTSF = BPTSF + f_{np,ATS}\left(\frac{v_{o,max}}{v_{o,max} + v_{o,adj}}\right)$$

$$PTSF = 71.3 - 21.0\left(\frac{842}{842 - 842}\right) = 81.8\%$$

Step 7: Estimate PFFS

This step is only used for Class III highways.

Step 8: Determine LOS and Capacity

LOS is determined by comparing the estimated values of ATS and PTSF with the criteria of Exhibit 15-3. An ATS of 38.0 mi/h suggests that LOS E will exist. A PTSF of 81.8% suggests that LOS E will exist. Thus, both criteria lead to the conclusion that the segment will operate at LOS E.

Capacity is determined by either Equation 15-12 or Equation 15-13, whichever produces the lower estimate. Note, however, that all adjustment factors for use in these equations are based on a directional flow rate greater than 900 pc/h. Thus, the grade factor will be 1.00 for both ATS and PTSF. The passenger car equivalent for trucks is 1.3 for ATS and 1.10 for PTSF; the passenger car equivalent for RVs is 1.1 for ATS and 1.00 for PTSF.

The adjustment factors for heavy vehicles are as follows:

$$f_{hv,ATS} = \frac{1}{1 - 0.14\,(1.3 - 1) + 0.04\,(1.1 - 1)} = 0.96$$

AR0073761

$$f_{HV,pre} = \frac{1}{1 + 0.14\,(1.0 \quad) + 0.04\,(1.0 \quad 1)} = 1.00$$

and

$$c_{i,pre} = 1700 \times f_{g,pre} \times f_{HV,pre} = 1{,}700 \times 1.00 \times 0.960 = 1{,}632 \text{ veh/h}$$

$$c_{prac} = 1700 \times f_{g,pre} \times f_{HV,pre} = 1{,}700 \times 1.00 \times 1.00 = 1{,}700 \text{ veh/h}$$

Obviously, the first value holds, and the directional capacity of this facility is 1,632 veh/h. Given the 50/50 directional distribution, the two-way capacity of the segment is 1,632 + 1,632 = 3,264 veh/h. Because this exceeds the limiting capacity of 3,200 pc/h, the directional capacity cannot be achieved with a 50/50 directional distribution. A total two-way capacity of 3,200 pc/h would prevail. In terms of prevailing conditions, the capacity would be 3,200 × 1.00 × 0.960 = 3,072 veh/h. With a 50/50 directional split, this implies a directional capacity of 3,072/2 = 1,536 veh/h.

Discussion

The two-lane highway segment as described is expected to operate poorly, with LOS F. The operation is poor despite the fact that demand is only 842/1,536 = 0.55 of capacity. Both ATS and PTSF are at unacceptable levels (0.8 mi/h and 81.8%, respectively). This situation again highlights the characteristic of two-lane highways of having poor operations at relatively low *v/c* ratios. This segment should clearly be examined for potential improvements.

Given the 50/50 directional split of traffic, results for the second direction would be identical.

EXAMPLE PROBLEM 2: CLASS II HIGHWAY LOS

The Facts

A segment of Class II highway is part of a scenic and recreational route and has the following known characteristics:

- Class II highway
- 1,050 veh/h (both directions)
- 70/30 directional split
- 5% trucks, 3% RVs
- PHF = 0.85
- 10 ft lanes; 2 ft shoulders
- BFFS = 55.0 mi/h
- Rolling terrain
- 10 access points/mi
- 40% no-passing zones

AR0073762

Comments

Computational steps 3 and 4, which relate to the estimation of average highway speed, will not be included. LOS for Class II highways depends solely on PTSF. The analysis will be conducted for both the 70% direction of flow and the 30% direction of flow. This is accomplished by merely reversing the analysis direction and opposing flows.

Step 1: Input Data

All input data have been summarized above.

Step 2: Estimate the FFS

FFS is estimated with Equation 15-2. Adjustment factors for lane and shoulder width (Exhibit 15-7) and access points per mile (Exhibit 15-8) are used.

Exhibit 15-7 is entered with 10-ft lanes and 2-ft shoulders. The resulting adjustment is 3.7 mi/h. Exhibit 15-8 is entered with 10 access points/mi. The resulting adjustment is 2.5 mi/h. The FFS is then estimated as follows.

$$FFS = 55.0 - 3.7 - 2.5 = 48.8 \text{ mi/h}$$

Steps 3 and 4

Steps 3 and 4 are not required for Class I highways.

Step 5: Demand Adjustment for PTSF

Equation 15-7 and Equation 15-8 are used to adjust analysis direction and opposing demands to flow rates under equivalent base conditions. With a 70/30 split of traffic, the two demands are as follows:

$$V_{o1} = V_1 = 1{,}050 \times 0.70 = 735 \text{ veh/h}$$

$$V_{o2} = V_2 = 1{,}050 \times 0.30 = 315 \text{ veh/h}$$

In this solution, directions will be referred to as 1 and 2. Since both directions are to be analyzed, their position as "analysis direction" and "opposing" will depend on which direction is under study.

Adjustment factors both for grades (Exhibit 15-16) and for heavy vehicles (Exhibit 15-18) are needed. Exhibit 15-16 and Exhibit 15-18 are entered with a directional flow rate of 735/0.85 = 865 veh/h (Direction 1) and 315/0.85 = 371 veh/h (Direction 2). Interpolation is required in both. The following values are obtained:

$f_{g,o1}$ = 1.00 (Direction 1); 0.89 (Direction 2)

E_T = 1.0 (Direction 1); 1.6 (Direction 2)

E_R = 1.0 (Direction 1); 3.0 (Direction 2)

The heavy vehicle adjustment factor for both directions is computed with Equation 15-8.

$$f_{HV,o1} = \frac{1}{1 + 0.05(1.00 - 1) + 0.07(1.00 - 1)} = 1.00$$

AR0073763

$$f_{hv,pass} = \frac{1}{1 + 0.05(1.6 - 1) + 0.07(1.00 - 1)} = 0.97$$

The adjusted demand flow rates are computed with Equation 15-7.

$$v_{1,pass} = \frac{735}{0.85 \times 1.00 \times 1.00} = 865 \text{ pc/h}$$

$$v_{2,pass} = \frac{315}{0.85 \times 0.89 \times 0.97} = 429 \text{ pc/h}$$

Step 6: Estimate PTSF

PTSF is estimated with Equation 15-9 and Equation 15-10 with values a and b taken from Exhibit 15-20 and $f_{hv,pass}$ taken from Exhibit 15-21.

Exhibit 15-20 is entered with opposing flow rates of 429 pc/h (for Direction 1) and 865 pc/h (for Direction 2). Both values must be interpolated. The resulting values are as follows:

Direction 1: $a = -0.0024$; $b = 0.915$

Direction 2: $a = -0.0046$; $b = 0.852$

Exhibit 15-21 is entered with the total demand flow rate of 865 + 429 = 1,294 pc/h, a directional split of 70/30, and 60% no-passing zones. Interpolation is required. The factor is the same for both Directions 1 and 2.

$$f_{d/np} = 23.0\%$$

BPTSF is computed with Equation 15-10:

$$BPTSF_1 = 100\left[1 - \exp(-0.0024 \times 865^{0.915})\right] = 68.9\%$$

$$BPTSF_2 = 100\left[1 - \exp(-0.0046 \times 429^{0.852})\right] = 51.0\%$$

The PTSF for each direction is computed with Equation 15-9:

$$PTSF_1 = 68.9 + 23.0\left(\frac{865}{865 - 429}\right) = 84.3\%$$

$$PTSF_2 = 51.0 + 23.0\left(\frac{429}{429 + 865}\right) = 58.6\%$$

Step 7

Step 7 is only used for Class III highways.

Step 8: Determine LOS and Capacity

The LOS is determined by comparing the PTSF values obtained with the criteria of Exhibit 15-3. Applying these criteria reveals that Direction 1 operates at LOS D, while Direction 2 operates at LOS C.

By using the adjustment selected for 2900 veh/h, capacity is computed with Equation 15-13:

$$c_{1,2\%} = 1{,}700 \times 1.00 \times 1.00 = 1{,}700 \text{ veh/h}$$

AR0073764

$$c_{3\,FSF} = 1{,}700 \times 1.00 \times 1.00 = 1{,}700 \text{ veh/h}$$

Discussion

The LOS is, at best, somewhat marginal on this two-lane highway segment, based solely on the PTSF.

The value of capacity must be carefully considered. If the directional capacities were expanded to two-way capacities based on the given demand split, the capacity in the 30% direction would imply a two-way capacity well in excess of the 3,200 pc/h limitation for both directions. Therefore, even though a capacity of 1,700 veh/h is possible in the 30% direction, it could not occur with a 70/30 demand split. In this case, the two-way capacity would be limited by the capacity in the 70% direction and would be 1,700/0.70 = 2,429 veh/h. The practical capacity for the 30% direction of flow is actually best estimated as 2,429 − 1,700 or 729 veh/h. Given that the 70/30 directional split holds, when the 30% direction reaches a demand flow rate of 729 veh/h, the opposing direction (the 70% side) would be at its capacity.

EXAMPLE PROBLEM 3: CLASS III HIGHWAY LOS

The Facts

A Class III two-lane highway runs through a rural community in level terrain. It has the following known characteristics:

- Class III highway
- Demand volume = 500 veh/h (both directions)
- 10% trucks; no RVs
- Measured FFS = 40 mi/h
- 12-ft lanes; 6-ft shoulders
- PHF = 0.88
- 80% no-passing zones
- 60/40 directional split
- 40 access points/mi
- Level terrain

Comments

Because this is a Class III highway, LOS will be based on PTSF. Thus, Steps 5 and 6, which relate to the estimation of PTSF, will not be used.

Step 1: Input Data

All input data are specified above.

Step 2: Estimate FFS

A measured FFS is specified: 40 mi/h.

AR0073765

Step 3: Demand Adjustment for ATS

The total demand volume of 900 veh/h must be separated into two directional flows. Since both directions will be evaluated, directions are labeled 1 and 2.

$$V_1 = 900 \times 0.60 = 540 \text{ veh/h}$$

$$V_2 = 900 \times 0.40 = 360 \text{ veh/h}$$

The adjusted demand flow rate in passenger cars per hour under equivalent base conditions is estimated with Equation 15-3. A grade adjustment factor is selected from Exhibit 15-9, and passenger car equivalents for trucks are selected from Exhibit 15-11. Both exhibits are entered with a demand flow rate in vehicles per hour.

$$v_1 = 540/0.88 = 614 \text{ veh/h}$$

$$v_2 = 360/0.88 = 409 \text{ veh/h}$$

The following values are selected from Exhibit 15-9 and Exhibit 15-11. In all cases, interpolation is required:

Value	Direction 1	Direction 2
$f_{g,ATS}$	1.00	1.00
E_T	1.1	1.3

Then, use of Equation 15-4 gives

$$f_{HV,ATS1} = \frac{1}{1 + 0.10(1.1 - 1)} = 0.99$$

$$f_{HV,ATS2} = \frac{1}{1 + 0.10(1.3 - 1)} = 0.97$$

Use of Equation 15-3 gives

$$v_{1,ATS} = \frac{540}{0.88 \times 1.00 \times 0.99} = 620 \text{ pc/h}$$

$$v_{2,ATS} = \frac{360}{0.88 \times 1.00 \times 0.97} = 422 \text{ pc/h}$$

Step 4: Estimate ATS

ATS is estimated with Equation 15-6 with an adjustment factor for no-passing zones taken from Exhibit 15-15. The adjustment factor is based on a 40-mi/h free-flow speed, 60% no-passing zones, and 80% no-passing demand flow rate of 422 pc/h (Direction 1) and 620 pc/h (Direction 2) gives the following:

$$f_{np,ATS1} = 2.4 \text{ mi/h}$$

$$f_{np,ATS2} = 1.6 \text{ mi/h}$$

AR0073766

Then, use of Equation 15-9 gives

$$ATS_1 = 40.0 - 0.00776(620 - 422) - 2.4 = 29.5 \text{ mi/h}$$

$$ATS_2 = 40.0 - 0.00776(422 + 620) - 1.6 = 30.3 \text{ mi/h}$$

Steps 5 and 6

Steps 5 and 6 are not used for Class III highways.

Step 7: Estimate PFFS

The LOS for Class III facilities is based on PFFS achieved, or ATS/FFS. For this segment, PFFS is as follows:

$$PFFS_1 = 29.5/40.0 = 73.8\%$$

$$PFFS_2 = 30.3/40.0 = 75.8\%$$

Step 8: Determine LOS and Capacity

From Exhibit 15-3, the LOS for Direction 1 is D, while the LOS for Direction 2 is C. The two values of PFFS are close, but the boundary condition between LOS C and D is 0.75. To be LOS C, PFFS must exceed 0.75, and it is just below the threshold in Direction 1 and just above the threshold in Direction 2.

Capacity is evaluated with adjustment factors for 2400 pc/h in level terrain. This makes all adjustment factors 1.00 (for ATS). Thus, the capacity in either direction is as follows:

$$c_{i,ATS} = c_{o,ATS} = 1{,}700 \times 1.00 \times 1.00 = 1{,}700 \text{ veh/h}$$

The two-way capacity values implied are 1,700/0.60 = 2,833 veh/h (Direction 1) and 1,700/0.40 = 4,250 veh/h (Direction 2). Obviously, the implied two-way capacity is the 2,833 veh/h. Moreover, this suggests that the directional capacity in Direction 2 cannot be achieved with a 60/40 demand split. Rather, the directional capacity in Direction 2 occurs when the capacity in Direction 1 occurs, or 2,833 × 0.40 = 1,133 veh/h.

Discussion

This segment of Class II two-lane highway operates just at the LOS C–D boundary. Depending on the length of the segment and local expectations, this may or may not be acceptable.

EXAMPLE PROBLEM 4: CLASS I HIGHWAY LOS WITH A PASSING LANE

The Facts

The 10-mi segment of the two-lane highway analyzed in Example Problem 1 will be improved with 2-mi passing lanes (one in each direction), both installed at 1.00 mi from the segment's beginning. The segment without a passing lane has already been analyzed, and the results of that analysis are listed below:

- Demand volume = 800 veh/h in each direction
- Demand flow rate (ATS) = 902 pc/h in each direction
- Demand flow rate (PTSF) = 842 pc/h in each direction

AR0073767

- FFS = 53.5 mi/h
- ATS = 38.6 mi/h
- PTSF = 81.8%
- Rolling terrain
- PHF = 0.95

Comments

Both directions will involve the same computations, since the directional distribution is 50/50, and in both cases, the passing lane will start 1.00 mi after the beginning of the segment (of 10 mi) and will end 3.00 mi after the beginning of the segment.

Step 1: Conduct an Analysis Without the Passing Lane

Completed as Example Problem 1.

Step 2: Divide the Segment into Regions

Exhibit 15-35 shows the division of the 6-mi segment into regions. The effective downstream length of the passing lane is selected from Exhibit 15-23 (value is different for ATS and PTSF) for a demand flow rate of 800/0.95 = 842 veh/h.

Exhibit 15-35
Region Lengths for Use in Example Problem 4

To Determine	L_d (mi)	L_{up} (mi)	L_{ds} (mi) Exhibit 15-23	L_e (mi) Equation 15-14
ATS	1.00	2.00	1.7	5.3
PTSF	1.00	2.00	4.7	2.3

Step 3: Determine the PTSF

The PTSF, as affected by the presence of a passing lane, is estimated with Equation 15-15 and an adjustment factor selected from Exhibit 15-28. The adjustment factor $f_{p,ovtk}$ is 0.62. Then

$$PTSF_a = \frac{PTSF\left[L_u + L_d + f_{p,ovtk} L_{up} + \left(\frac{1 + f_{p,ovtk}}{2}\right) L_{ds}\right]}{L_t}$$

$$PTSF_{pl} = \frac{81.8\left[1.0 + 2.3 + (0.62 \times 2.00) + \left(\frac{1 + 0.62}{2}\right) 4.7\right]}{10}$$

$$PTSF_w = \frac{81.8(3.3 + 1.24 + 3.81)}{10} + \frac{81.8 \times 8.35}{10} = 68.3\%$$

Step 4: Determine the ATS

The ATS, as affected by the presence of a passing lane, is found with Equation 15-17 and an adjustment factor selected from Exhibit 15-28. The adjustment factor selected is 1.11. Then

AR0073768

$$ATS_{pt} = \frac{ATSL_t}{L_s + L_a + \left(\frac{L_a}{f_{LA,ATS}}\right) \div \left(\frac{2L_a}{1 + f_{LA,ATS}}\right)}$$

$$ATS_{pt} = \frac{38.6 \times 2.0}{1.00 + 5.3 + \left(\frac{2.00}{1.12}\right) + \left(\frac{2 \times 11.7}{1 + 1.12}\right)}$$

$$ATS_{pt} = \frac{38.6 \times 11.0}{6.30 + 1.80 + 1.61} = \frac{38.6 \times 11.0}{9.71} = 39.7 \text{ mi/h}$$

Step 5: Determine the LOS

Exhibit 15-3 shows that the LOS, as determined by PTSF, has improved to D. The LOS determined by ATS remains E. Thus, while PTSF has improved significantly, the ATS has not improved enough to improve the overall LOS, which remains E.

Discussion

Adding a 2-mi passing lane to a 20-mi segment of Class I highway operating at LOS E was insufficient to improve the overall LOS, although the PTSF did improve from 61.8% to 68.0%. It is likely that a longer (or a second) passing lane would be needed to improve the ATS sufficiently to result in LOS C or LOS D.

EXAMPLE PROBLEM 5: TWO-LANE HIGHWAY BICYCLE LOS

A segment of two-lane highway (without passing lanes) is being evaluated for potential widening, resurfacing, and repaving. Analyze the impacts of the proposed project on the bicycle LOS in the peak direction.

The Facts

The roadway currently has the following characteristics:

- Lane width = 12 ft
- Shoulder width = 2 ft
- Pavement ramp = 3 (four)
- Posted speed limit = 50 mi/h
- Hourly directional volume = 500 veh/h (no growth is expected)
- Percentage of heavy vehicles = 5%
- PHF = 0.90
- No on-highway parking

AR0073769

The proposed roadway design has the following characteristics:

- Lane width = 12 ft
- Shoulder width = 6 ft
- Pavement rating = 5 (very good)
- Posted speed limit = 55 mi/h
- No on-highway parking

Step 1: Gather Input Data

All data needed to perform the analysis are listed above.

Step 2: Calculate the Directional Flow Rate in the Outside Lane

By using the hourly directional volume and the PHF, calculate the directional demand flow rate with Equation 15-24. Because this is a two-lane highway segment without a passing lane, the number of directional lanes N is 1. Because traffic volumes are not expected to grow over the period of the analysis, v_d is the same for both current and future conditions.

$$v_{d,i} = \frac{V}{PHF \times N}$$

$$v_{d,i} = \frac{500}{0.90 \times 1} = 556 \text{ veh/h}$$

Step 3: Calculate the Effective Width

For current conditions, the hourly directional demand V is greater than 100 veh/h and the paved shoulder width is 2 ft; therefore, Equation 15-27 and Equation 15-28 are used to determine the effective width of the outside lane. Under future conditions, the paved shoulder width will increase to 6 ft; therefore, Equation 15-26 and Equation 15-28 are used.

For current conditions:

$$W_v = W_{v,i} + W = 12 \text{ ft} + 2 \text{ ft} = 14 \text{ ft}$$

$$W_s = W + (\%OHP(2 \text{ ft} - W_v))$$

$$W_s = 14 \text{ ft} + (0 \times (2 \text{ ft} + 2 \text{ ft})) = 14 \text{ ft}$$

Under the proposed design:

$$W_v = W_{v,i} + W = 12 \text{ ft} + 6 \text{ ft} = 18 \text{ ft}$$

$$W_s = W_v + W - 2 \times (\%OHP(2 \text{ ft} + W_v))$$

$$W_s = 18 \text{ ft} + 6 \text{ ft} - 2 \times (0 \times (2 \text{ ft} + 6 \text{ ft})) = 24 \text{ ft}$$

Step 4: Calculate the Effective Speed Factor

Equation 15-30 is used to calculate the effective speed factor. Under current conditions:

$$f_s = 1.1199 \ln(S_v - 20) + 0.8103$$

AR0073770

$$S_a = 1.1199 \ln(50 - 20) + 0.8103 - 4.62$$

Under the proposed design:

$$S_a = 1.1199 \ln(55 - 20) + 0.8103 = 4.79$$

Step 5: Determine the LOS

Equation 15-31 is used to calculate the bicycle LOS score, which is then used in Exhibit 15-4 to determine the LOS. Under existing conditions:

$$BLOS = 0.507 \ln(v_{15,a}) + 0.1999 S_a (1 + 10.38 HV)^2 + 7.066(1/P)^2 - 0.005(W_v)^2 + 0.057$$

$$BLOS = 0.507 \ln(556) + 0.1999(4.62)(1 + 10.38 \times 0.05)^2 + 7.066(1/3)^2 - 0.005(14)^2 + 0.057$$

$$BLOS = 3.205 + 2.131 + 0.785 - 0.980 + 0.057 = 5.20$$

Therefore, the bicycle LOS for existing conditions is LOS F. Use of the same process for the proposed design results in the following:

$$BLOS = 0.507 \ln(556) + 0.1999(4.79)(1 + 10.38 \times 0.05)^2 + 7.066(1/5)^2 - 0.005(24)^2 + 0.057$$

$$BLOS = 3.205 + 2.209 + 0.283 - 2.880 + 0.057 = 2.87$$

The corresponding LOS for the proposed design is LOS C.

Discussion

Although the posted speed would increase as a result of the proposed design, this negative impact on bicyclists would be more than offset by the proposed shoulder widening, as indicated by the improvement from LOS F to LOS C.

AR0073772

APPENDIX A: DESIGN AND OPERATIONAL TREATMENTS

Two-lane highways make up approximately 80% of all paved rural highways in the United States but carry only about 30% of all traffic. For the most part, two-lane highways carry light volumes and experience few operational problems. Some two-lane highways, however, periodically experience significant operational and safety problems brought about by a variety of traffic, geometric, and environmental causes. Such highways may require design or operational improvements to alleviate congestion.

When traffic operational problems occur on two-lane highways, many agencies consider widening to four lanes. Another effective method for alleviating operational problems is to provide passing lanes at intervals in each direction of travel or to provide climbing lanes on steep upgrades. Passing and climbing lanes cannot increase the capacity of a two-lane highway, but they can improve its LOS. Short sections of four-lane highway can function as a pair of passing lanes in opposite directions of travel. Operational analysis procedures for passing and climbing lanes are included in this chapter.

A number of other design and operational treatments are effective in alleviating operational congestion on two-lane highways, including:

- Turnouts,
- Shoulder use,
- Wide cross sections,
- Intersection turn lanes, and
- Two-way left-turn lanes.

No calculation methodologies are provided in this chapter for these treatments; however, the treatments are discussed below to indicate their potential for improving traffic operations on two-lane highways.

TURNOUTS

A turnout is a widened, unobstructed shoulder area on a two-lane highway that allows slow-moving vehicles to pull out of the through lane so that vehicles following may pass. Turnouts are relatively short, generally less than 625 ft. At a turnout, the driver of a slow-moving vehicle that is delaying one or more following vehicles is expected to pull out of the through lane, allowing the vehicles to pass. The driver of the slow-moving vehicle is expected to remain in the turnout only long enough to allow the following vehicle to pass before returning to the travel lane. When there are only one or two following vehicles, this maneuver can usually be completed smoothly, with no need for the vehicle to stop at the turnout. When there are three or more following vehicles, however, the vehicle in the turnout will generally have to stop to allow all vehicles to pass. In this case, the driver of the slower vehicle is expected to stop before the end of the turnout, so that the vehicle will develop some speed before reentering the lane. Signs inform drivers of the turnout's location and reinforce the legal requirements concerning turnout use.

AR0073773

Turnouts have been used in several countries to provide additional passing opportunities on two-lane highways. In the United States, turnouts have been used extensively in western states. Exhibit 15-A1 illustrates a typical turnout.

Exhibit 15-A1
Typical Turnout Illustrated

Turnouts may be used on nearly any type of two-lane highway that offers limited passing opportunities. To avoid confusing drivers, turnouts and passing lanes should not be intermixed on the same highway.

A single well-designed and well-located turnout can be expected to accommodate 20% to 90% of the number of passes that would occur on a 1.6-km passing lane in level terrain (*A1, A2*). Turnouts have been found to operate safely, with experts (*A2, A4*) noting that turnout accidents occur at a rate of only 1 per 80,000 to 400,000 uses.

SHOULDER USE

The primary purpose of the shoulder on two-lane highways is to provide a stopping and recovery area for disabled or errant vehicles. However, paved shoulders also may be used to increase passing opportunities on two-lane highways.

In some parts of the United States and Canada, if the paved shoulders are adequate, there is a long-standing custom for slower vehicles to move to the shoulder when a vehicle approaches from the rear. The slower vehicle then returns to the travel lane once the passing vehicles has cleared. The custom is regarded as a courtesy and requires little or no restriction in speed by either motorist. A few highway agencies encourage drivers of slow-moving vehicles to use the shoulder in this way because it improves the LOS of two-lane highways without the expense of adding passing lanes or widening the highway. On the other hand, there are agencies that discourage this practice because their shoulders are not designed for frequent use by heavy vehicles.

One highway agency in the western United States generally does not permit shoulder use by slow-moving vehicles but designates specific sections on which the shoulder may be used for this purpose. These shoulder segments range in length from 0.2 to 3.0 mi and are identified by traffic signs.

Research (*A1, A2*) has shown that a shoulder-use segment is about 20% as effective in reducing platoons as a passing lane of comparable length.

WIDE CROSS SECTIONS

Two-lane highways with lanes about 50% wider than normal have been used in several European countries as a less expensive alternative to passing lanes. Sweden, for example, built approximately 500 mi of roadways with two 4.5-m travel lanes and relatively narrow (1.5-ft) shoulders. The wider lane permits faster vehicles to pass slower vehicles while encroaching only slightly on the opposing lane of traffic. Opposing vehicles must move toward the shoulder to permit such maneuvers. Roadway segments with wider lanes can be provided at

AR0073774

intervals. The passing lanes do not increase passing opportunities on two-lane highways.

Research has shown that speeds at low traffic volumes tend to increase on wider lanes, but the effect on speeds at higher volumes varies (*A6*). More than 70% of drivers indicated that they appreciate the increased passing opportunities available on the wider lanes. No safety problems have been associated with the wider lanes.

Formal procedures have not yet been developed for evaluating the traffic operational effectiveness of wider lanes in increasing the passing opportunities on a two-lane highway. It is reasonable to estimate the traffic operational performance on a directional two-lane highway segment containing wider lanes as midway between the segment with and without a passing lane of comparable length.

INTERSECTION TURN LANES

Intersection turn lanes are desirable at selected locations on two-lane highways to reduce delays to through vehicles caused by turning vehicles and to reduce turning accidents. Separate right- and left-turn lanes may be provided, as appropriate, to remove turning vehicles from the through travel lanes. Left-turn lanes, in particular, provide a protected location for turning vehicles to wait for an acceptable gap in the opposing traffic stream. This reduces the potential for collisions from the rear and may encourage drivers of left-turning vehicles to wait for an adequate gap in opposing traffic before turning. Exhibit 15-A2 shows a typical two-lane highway with left-turn lanes at an intersection.

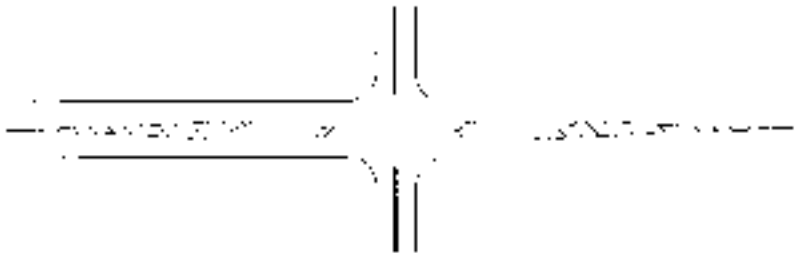

Exhibit 15-A2
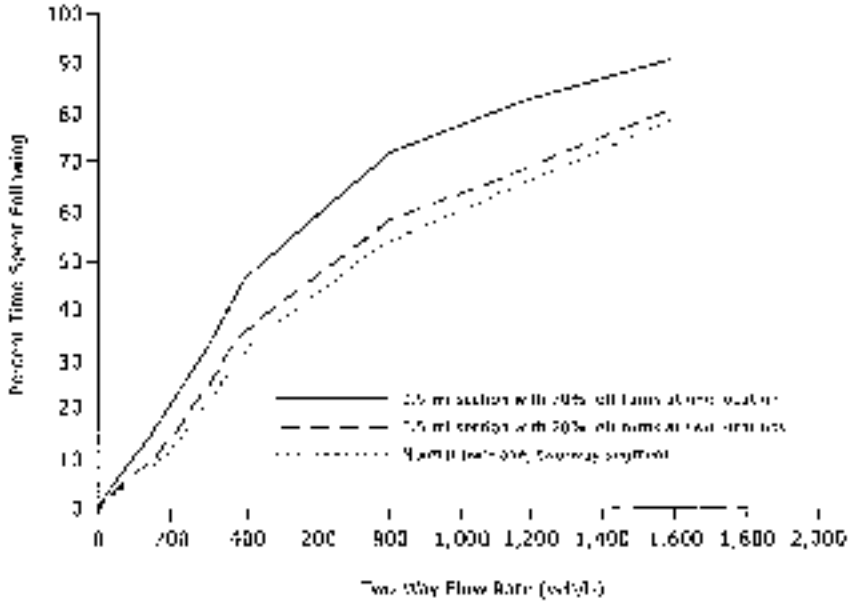
Typical Two-Lane Highway
Intersection with Left-Turn Lane

Research has recommended specific operational warrants for left-turn lanes at intersections on two-lane highways based on the directional volumes and the percentage of left turns (*A6*). The HCM's intersection analysis methodologies can be used to quantify the effects of intersection turn lanes on signalized and unsignalized intersections. There is no methodology, however, for estimating the effect of turn lanes on average highway speed. Modeling of intersection delays shows the relative magnitude of likely effects of turning delays on PTSF (*A7*); the results are shown in Exhibit 15-A3. The top line in the exhibit shows that turning vehicles can increase PTSF substantially over a short road segment. However, when these effects are averaged over a longer road segment, the increase in PTSF is greatly reduced, as indicated by the dashed line in the exhibit. The provision of intersection turn lanes has the potential to minimize these effects.

AR0073775

Exhibit 15-A3
Effect of Turning Delays at Intersections on FTSF

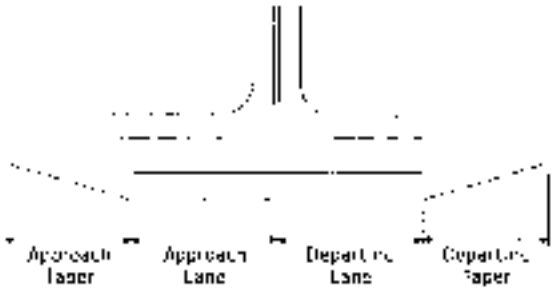


Source: Hoban (44).

Several agencies in the United States provide shoulder bypass lanes at three-leg intersections as a low-cost alternative to a left-turn lane. As shown in Exhibit 15-A4, a portion of the paved shoulder may be marked as a lane for through traffic to bypass vehicles that are slowing or stopped to make a left turn. Bypass lanes may be appropriate for intersections that do not have volumes high enough to warrant a left-turn lane.

The delay benefits of shoulder bypass lanes have not been quantified, but field studies have indicated that 97% of drivers who need to avoid delay will make use of an available shoulder bypass lane. One state has reported a marked decrease in rear-end collisions at intersections where shoulder bypass lanes were provided (*78*).

Exhibit 15-A4
Typical Shoulder Bypass Lane at a Three-Leg Intersection on a Two-Lane Highway



TWO-WAY LEFT-TURN LANES

A two-way left-turn lane (TWLTL) is a paved area in the highway median that extends continuously along a roadway segment and is marked to provide a deceleration and storage area for vehicles traveling in either direction that are making left turns at intersections and driveways.

TWLTLs have been used for many years on urban and suburban streets with high driveway densities and turning demands to improve safety and reduce

AR0073776

delays to through vehicles. TWLTLs can be used on two-lane highways in rural and urban fringe areas to obtain the same types of operational and safety benefits—particularly on Class III two-lane highways. Exhibit 15-A5 illustrates a typical TWLTL.

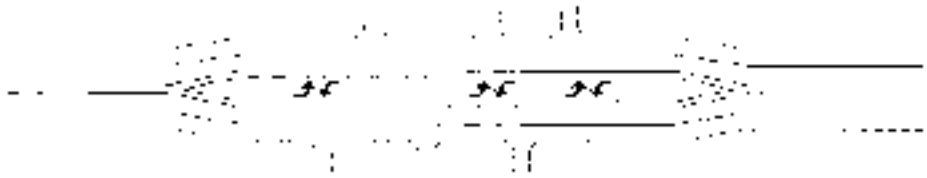


Exhibit 15-A5
Typical TWLTL on a Two-Lane Highway

There is no formal methodology for evaluating the traffic operational effectiveness of a TWLTL on a two-lane highway. Research has found that delay reduction provided by a TWLTL depends on both the left-turn demand and the opposing traffic volume (*A2*). Without a TWLTL or other left-turn treatment, vehicles that are slowing or stopped to make a left turn may create delays for following through vehicles. A TWLTL minimizes these delays and makes the roadway segment operate more like two-way and directional segments with 100% no-passing zones. These research results apply to sites that do not have paved shoulders available for following vehicles to bypass turning vehicles. Paved shoulders may alleviate as much of the delay as a TWLTL.

Research has found little delay reduction at rural TWLTL segments with traffic volumes below 300 vph in one direction (*A2*). At several low-volume sites, no reduction was observed. The highest delay reduction observed was 3.4 s per left-turning vehicle. Therefore, at low-volume rural sites, TWLTLs should be considered for reducing accidents but should not be expected to improve the operational performance of the highway.

At higher-volume urban fringe sites, greater delay reduction was found with TWLTLs on a two-lane highway. Exhibit 15-A6 shows the expected delay reduction per left-turning vehicle as a function of opposing volume. As the delay reduction increases, a TWLTL can be justified for improving both safety and operations.

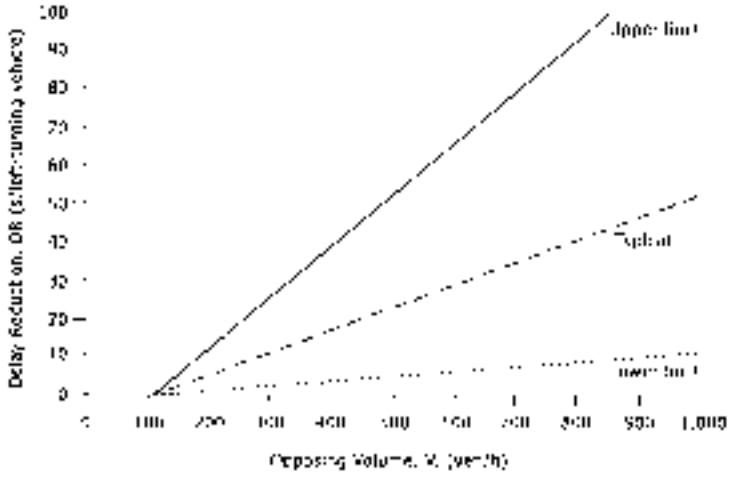

Exhibit 15-A6
Estimated Delay Reduction with a TWLTL on a Two-Lane Highway Without Paved Shoulders

All-way stop-controlled, 10-15, 16-3
Alternative lane, 10-33, 10-42, 12-43, 12-44, 12-46, 12-47, 12-48, 12-51, 12-28, 12-29, 12-28, 12-29, 12-30, 13-31, 13-33, 13-35, 14-26
Analysis hour, 11-8, 11-26, 12-31, 13-29, 13-31, 14-6, 14-24, 15-16
Analysis period, 10-7, 10-16, 11-17, 10-23, 11-8, 11-21, 11-24, 12-17, 12-18, 13-6, 14-5, 14-20, 14-23, 15-9, 15-10, 15-31, 15-35, 15-50, 15-61
Annual average daily traffic (AADT), 11-21, 12-50, 14-7, 15-12
Auxiliary lane, 13-1, 10-11, 10-21, 10-25, 10-42, 11-48, 11-26, 12-4, 12-5, 12-6, 12-7, 22-37
Average grade, 11-17, 11-35, 11-45, 14-17, 15-14
Average travel speed, 9-5, 15-21, 15-33, 15-51

B

Barrier, 1-10, 12-8, 12-18, 14-8, 14-24, 15-5
Base conditions, 10-31, 11-32, 11-1, 11-3, 11-4, 11-15, 11-18, 11-19, 11-21, 11-30, 11-33, 11-34, 11-35, 11-41, 13-9, 14-1, 14-2, 14-4, 14-13, 14-18, 14-33, 14-28, 14-28, 14-33, 14-34, 14-35, 14-36, 14-37, 15-4, 15-5, 15-10, 15-16, 15-17, 15-25, 15-26, 15-27, 15-36, 15-45, 15-49, 15-52
Base length, 10-2, 10-27, 12-3
Basic freeway segment, 10-1, 11-1, 12-3, 13-3, 14-2
Bicycle, 14-3, 14-7, 14-8, 14-14, 11-38, 15-6, 15-8, 15-9, 15-36, 15-55, 15-59
Bicycle level of service (LOS), 14-1, 14-3, 14-7, 14-8, 14-9, 14-18, 15-11, 15-12, 15-36, 15-38, 15-44, 15-45, 15-57
Bottleneck, 1-44
Breakdown, 10-4, 10-8, 10-9, 10-10, 11-1, 11-3, 11-7, 11-18, 11-19, 12-16, 12-44, 12-49, 15-2, 15-9, 15-30, 15-35, 14-3
Bus stop, 14-8
Bypass lane, 1-42

C

Calibration, 10-44, 10-45, 12-15, 12-28, 12-30, 13-5, 13-26, 13-34, 14-13, 15-2
Capacity, 10-1, 11-1, 11-3, 11-4, 12-3, 13-3, 14-1, 14-4, 15-1, 15-5
Class III two-lane highways, 18-3, 18-15, 18-17, 18-22, 18-23, 18-29
Climbing lane, 1-9, 1-36, 11-39, 11-1, 13-11, 15-28, 15-33, 15-34, 15-39, 15-59
Cloverleaf interchange, 21-20, 21-29, 22-3, 22-29
Composite grade, 10-49, 12-15, 11-16, 11-17, 11-22, 11-36, 11-45, 11-46, 11-47, 14-11, 14-17
Computational engine, 1-17, 1-19

AR0073779

Congestion, 10-14, 10-16, 10-21, 10-24, 10-25, 10-33, 10-43, 10-50, 10-54, 10-58, 10-61, 11-6, 11-25, 12-4, 12-28, 13-2, 13-7, 13-14, 14-42, 15-8, 15-10, 15-59
Congestion pricing, 10-14
Control condition, 10-4, 10-6, 10-10
Corridor, 10-17, 12-41
Crawl speed, 13-14, 13-15, 13-32, 13-46, 13-47, 14-15, 15-20, 15-21, 15-24
Critical segment, 10-6, 10-8, 10-10

D

Daily service volume, 10-12, 11-25, 11-41, 12-31, 14-25, 15-40
Deceleration lane, 10-20, 10-40, 12-3, 13-1, 13-3, 13-5, 13-6, 13-10, 13-12, 13-14, 13-20, 13-21, 13-22, 13-24, 13-25, 13-29, 13-31, 13-33, 13-34, 13-39, 13-41
Default value, 10-28, 10-30, 10-45, 11-10, 11-21, 11-22, 11-23, 11-24, 11-38, 11-45, 11-13, 12-5, 12-25, 12-26, 12-32, 13-28, 13-30, 13-34, 13-36, 13-38, 13-43, 14-30, 14-20, 14-21, 14-22, 14-35, 15-9, 15-10, 15-15, 15-36, 15-39, 15-43
Delay, 10-29, 10-43, 11-26, 12-29, 13-31, 15-1, 15-2, 15-7, 15-62, 15-63
  see also Traffic delay
Demand
  see Demand flow rate
Demand flow rate, 10-6, 10-5, 10-6, 11-1, 11-4, 11-7, 12-1, 12-4, 14-4, 14-6, 15-5, 15-10
Demand estimation, 13-38, 14-9
Demand-to-capacity ratio, 10-17, 10-32, 10-43, 10-51, 10-55, 10-57, 10-59, 11-40, 11-6
Density, 10-3, 10-4, 11-4, 11-5, 12-7, 13-4, 13-5, 14-1, 14-5, 15-2, 15-3
Design hour, 12-26
Design speed, 14-11, 15-9, 15-15
D-factor, 10-11, 10-12, 11-8, 11-24, 11-41, 12-31, 13-39, 14-6, 14-23, 14-28, 15-41
Diamond interchange, 11-20, 13-19
Directional design hour volume, 12-26
Directional distribution, 15-27, 15-28, 15-43, 15-54
Directional flow rate, 15-33, 15-47, 15-64
Directional segment, 15-5, 15-11, 15-12, 15-24, 15-34, 15-35, 15-63
Directional split, 10-10, 15-26, 15-44, 15-47, 15-48, 15-50, 15-51
Diverge, 10-1, 10-2, 11-1, 12-2, 12-3, 12-5, 13-1, 13-2, 15-3
Diverge segment
  see Merge and diverge segment
Downstream, 10-2, 10-3, 11-1, 11-2, 12-3, 13-2, 13-3, 13-4, 15-6
Driver population factors, 10-16, 11-10, 11-38, 11-39, 11-40, 11-42, 13-5, 13-37, 13-44, 13-53, 14-10, 14-24, 14-25, 14-26

E

Entrance ramp, 13-25, 10-27, 10-41, 12-9, 12-29
Environmental conditions, 10-29
Exit ramp, 12-29, 13-25
Extent of congestion, 10-43, 11-25, 12-28, 13-53

F

Facility, 10-4, 10-5, 10-6
Flow rate, 10-3, 10-4, 10-5, 11-1, 12-3, 12-1, 13-2, 13-4, 14-3, 14-4, 15-1
Follower density, 13-47
Free-flow speed, 10-2, 10-4, 13-4, 10-6, 10-7, 10-29, 10-31, 10-40, 10-45, 10-46, 10-47, 11-3, 11-4, 12-1, 12-11, 13-1, 13-2, 14-2, 15-7, 15-8, 15-9, 15-24, 15-25, 15-31, 15-69
Freeway, auxiliary lane, 12-4, 12-5, 12-6, 12-7
Freeway diverge segment, 10-4
Freeway facility, 10-1, 10-3
Freeway junction, 10-20, 11-22, 13-1, 13-2, 13-3, 13-4
Freeway section, 10-28, 10-34, 10-39, 10-7
Freeway weaving segment, 12-2, 12-8, 12-23, 12-25, 12-27, 12-28, 12-38
  see also Weaving, Multiple weaving segment, One-sided weaving

G

General terrain, 10-44, 11-8, 11-14, 11-15, 11-22, 14-6, 14-14, 14-15, 15-11, 15-19, 15-23, 15-24
Generalized service volume table, 10-11, 10-12, 10-13, 10-14
  see also Daily service volume
Gore area, 10-39, 12-3, 12-6, 12-13, 12-42, 13-25
Grade factor, 10-11

AR0073780

H

Headway, 10-15, 11-23, 11-26, 13-32, 13-35
Heavy vehicle, 10-6, 10-7, 11-2, 12-25, 13-4, 13-6, 14-2, 14-10, 15-9, 15-10, 15-11
High-occupancy vehicle (HOV), 10-14, 10-17

I

Incident, 10-14, 10-30, 10-31, 10-32, 11-6, 11-28, 15-6
Influence area, 10-2, 10-20, 10-21, 10-22, 10-23, 10-48, 10-49, 11-1, 12-16, 13-2, 13-3, 13-4, 13-7, 13-8, 13-9, 13-10, 13-11, 13-12
Interchange, 11-20, 11-29, 13-1, 13-11, 13-14, 13-20, 13-24, 13-41, 13-50, 13-51, 13-59
Interchange density, 12-11, 12-29, 12-30, 12-41
Interchange ramp terminal, 13-19
Intersection delay, 17-61

K

K-factor, 10-11, 11-24, 11-41, 12-4, 13-10, 14-6

L

Lane 1, 13-3, 13-21, 13-50
Lane balance, 12-6, 12-7, 12-8
Lane distribution, 13-46, 13-10, 13-11, 13-12, 13-23, 13-40, 13-41, 13-45, 13-50
Lane utilization, 11-26, 13-33
Lane width, 10-6, 10-13, 10-20, 10-28, 10-40, 10-48, 11-2, 11-4, 11-11, 12-13, 12-27, 13-5, 14-2, 14-10, 15-12
Lateral clearance, 10-6, 10-13, 10-12, 11-8, 11-10, 13-4, 13-5, 14-2, 14-6
Level of service (LOS), 10-1, 10-8, 10-9, 11-1, 11-9, 11-15, 11-17, 12-9, 12-10, 12-13, 13-2, 13-4, 13-7, 13-8, 13-9, 14-1, 14-3, 14-4, 14-5, 14-7, 14-8, 14-9, 15-2, 15-5, 15-7, 15-8, 15-9
Level of service score (LOS score), 15-58
Level terrain, 10-35, 11-17, 11-39, 11-54, 12-32, 13-37, 13-44, 13-49, 13-53, 14-12, 14-27, 14-28, 14-29, 14-30, 14-31, 14-32, 15-16, 15-17, 15-19, 15-23, 15-26, 15-41, 15-42, 15-44, 15-51, 15-53, 15-60
Loop ramp, 13-5
LOS
see Level of service (LOS)

M

Macroscopic model, 12-29
Mainline, 13-8, 10-19, 10-21, 10-27, 10-35, 10-36, 10-37, 10-38, 10-49, 10-54, 10-59, 11-8, 12-5, 13-1, 13-3, 13-4, 13-5, 13-26, 13-27, 13-34
Mainline output, 10-57
Major diverge area, 13-26, 13-27
Major merge area, 13-26
Major weaving segment, 12-5, 12-7, 12-8, 12-31
Managed lanes, 6-48
Maximum weaving length, 12-31, 12-61, 12-28, 12-29, 12-61
Median, 14-1, 14-2, 14-6, 14-8, 14-10, 14-11, 14-12, 14-21, 14-30, 14-32, 14-33, 14-34, 15-62
Merge, 10-1, 10-3, 10-5, 10-4, 11-1, 11-6, 11-9, 12-1, 12-2, 12-3, 12-5, 12-7, 13-1, 13-2, 13-3, 13-4
Merge segment
see Merge and diverge segment
Merge and diverge segment, 12-1, 10-2, 10-21, 10-45, 10-49, 12-1
Microscopic model, 11-26, 12-29, 13-33
Mobility, 15-2, 15-7
Mountainous terrain, 11-15, 14-15, 15-11
Multilane highway, 14-1
Multiple weaving segments, 12-21

N

Nonweaving flow, 10-46, 12-20, 12-25, 12-32
Nonweaving movement, 12-2, 12-28, 12-29
Nonpassing zone, 15-1, 15-5, 15-9

O

On-ramp, 10-1, 10-3, 10-4, 11-1, 11-4, 12-4, 12-5, 12-6, 15-1, 13-2, 13-5, 13-4
One-sided weaving segment, 12-4, 12-5, 12-6, 12-10, 12-14, 12-15
On ramp, 10-2, 10-3, 11-1, 11-4, 12-4, 12-5, 12-6, 13-1, 13-2, 13-4, 13-5
Opposing flow rate, 15-7, 15-21, 15-22, 15-46, 15-50

AR0073781

Oversaturated flow, 10-17, 10-43, 11-2, 13-7

P

Passenger-car equivalent, 10-27, 11-19, 14-14
Passing lane, 14-8, 15-9, 15-21, 15-28, 15-29, 15-30, 15-41, 15-52, 15-54, 15-57, 15-59, 15-62, 15-64, 15-65, 15-66, 15-68, 15-69, 15-71
Passing sight distance, 15-5
Pedestrian, 14-8
Percent time spent following, 15-5, 15-25, 15-31, 15-35
Performance measure, 10-32, 10-34, 10-36, 10-49, 10-51, 10-52, 10-54, 10-56, 10-61, 11-7, 11-23, 11-27, 12-26, 13-22, 13-33, 15-35, 15-39, 15-43
Platoon, 11-11, 12-21, 13-1, 13-27, 14-13, 15-6
Power-to-mass ratio, 10-20, 10-43, 11-2, 11-13, 12-4, 12-15, 14-13, 14-14, 14-21, 15-18, 15-19, 15-27, 15-28, 15-38

Q

Quality of service, 15-1, 15-13, 15-38, 15-42
Queue, 10-5, 10-15, 10-24, 10-39, 10-47, 10-48, 10-49, 10-54, 10-55, 10-60, 11-2, 11-7, 11-26, 12-29, 12-30, 13-18, 13-33
Queue discharge flow, 11-2
Queue length, 10-36, 10-43, 11-26, 12-29, 13-30

R

TRANSPORTATION RESEARCH BOARD
2010 EXECUTIVE COMMITTEE*

Chair: Michael R. Morris, Director of Transportation, North Central Texas Council of Governments, Arlington

Vice Chair: Neil J. Pedersen, Administrator, Maryland State Highway Administration, Baltimore

Executive Director: Robert E. Skinner, Jr., Transportation Research Board

J. Barry Barker, Executive Director, Transit Authority of River City, Louisville, Kentucky

Allen D. Biehler, Secretary, Pennsylvania Department of Transportation, Harrisburg

Larry L. Brown, Sr., Executive Director, Mississippi Department of Transportation, Jackson

Deborah H. Butler, Executive Vice President, Planning, and CIO, Norfolk Southern Corporation, Norfolk, Virginia

William A. V. Clark, Professor, Department of Geography, University of California, Los Angeles

Eugene A. Conti, Jr., Secretary of Transportation, North Carolina Department of Transportation, Raleigh

Nicholas J. Garber, Henry L. Kinnier Professor, Department of Civil Engineering, and Director, Center for Transportation Studies, University of Virginia, Charlottesville

Jeffrey W. Hamiel, Executive Director, Metropolitan Airports Commission, Minneapolis, Minnesota

Paula J. Hammond, Secretary, Washington State Department of Transportation, Olympia

Edward A. (Ned) Helme, President, Center for Clean Air Policy, Washington, D.C.

Adib K. Kanafani, Cahill Professor of Civil Engineering, University of California, Berkeley (Past Chair, 2009)

Susan Martinovich, Director, Nevada Department of Transportation, Carson City

Debra L. Miller, Secretary, Kansas Department of Transportation, Topeka (Past Chair, 2008)

Sandra Rosenbloom, Professor of Planning, University of Arizona, Tucson

Tracy L. Rosser, Vice President, Regional General Manager, Wal-Mart Stores, Inc., Mandeville, Louisiana

Steven T. Scalzo, Chief Operating Officer, Marine & Southeast Operations, Norfolk, Virginia

Henry G. (Gerry) Schwartz, Jr., Chairman (ret.), Jacobs/Sverdrup Civil, Inc., St. Louis, Missouri

Beverly A. Scott, General Manager and Chief Executive Officer, Metropolitan Atlanta Rapid Transit Authority, Atlanta, Georgia

David Seltzer, Principal, Mercator Advisors LLC, Philadelphia, Pennsylvania

Daniel Sperling, Professor of Civil Engineering and Environmental Science and Policy; Director, Institute of Transportation Studies; and Interim Director, Energy Efficiency Center, University of California, Davis

Kirk T. Steudle, Director, Michigan Department of Transportation, Lansing

Douglas W. Stotlar, President and Chief Executive Officer, Con-Way, Inc., Ann Arbor, Michigan

C. Michael Walton, Ernest H. Cockrell Centennial Chair in Engineering, University of Texas, Austin (Past Chair, 1991)

Peter H. Appel, Administrator, Research and Innovative Technology Administration, U.S. Department of Transportation (ex officio)

J. Randolph Babbitt, Administrator, Federal Aviation Administration, U.S. Department of Transportation (ex officio)

Rebecca M. Brewster, President and COO, American Transportation Research Institute, Smyrna, Georgia (ex officio)

George Bugliarello, Professor Emeritus and University Professor, Polytechnic Institute of New York University, Brooklyn; Chancellor, National Academy of Engineering, Washington, D.C. (ex officio)

Anne S. Ferro, Administrator, Federal Motor Carrier Safety Administration, U.S. Department of Transportation (ex officio)

LeRoy Gishi, Chief, Division of Transportation, Bureau of Indian Affairs, U.S. Department of the Interior, Washington, D.C. (ex officio)

Edward R. Hamberger, President and CEO, Association of American Railroads, Washington, D.C. (ex officio)

John C. Horsley, Executive Director, American Association of State Highway and Transportation Officials, Washington, D.C. (ex officio)

David T. Matsuda, Deputy Administrator, Maritime Administration, U.S. Department of Transportation (ex officio)

Victor M. Mendez, Administrator, Federal Highway Administration, U.S. Department of Transportation (ex officio)

William W. Millar, President, American Public Transportation Association, Washington, D.C. (ex officio, Past Chair, 1998)

Tara O'Toole, Under Secretary for Science and Technology, U.S. Department of Homeland Security (ex officio)

Robert J. Papp (Adm.), Commandant, U.S. Coast Guard, U.S. Department of Homeland Security (ex officio)

Cynthia L. Quarterman, Administrator, Pipeline and Hazardous Materials Safety Administration, U.S. Department of Transportation (ex officio)

Peter M. Rogoff, Administrator, Federal Transit Administration, U.S. Department of Transportation (ex officio)

David L. Strickland, Administrator, National Highway Traffic Safety Administration, U.S. Department of Transportation (ex officio)

Joseph C. Szabo, Administrator, Federal Railroad Administration, U.S. Department of Transportation (ex officio)

Polly Trottenberg, Assistant Secretary for Transportation Policy, U.S. Department of Transportation (ex officio)

Robert F. Van Antwerp (Lt. Gen.), U.S. Army, Chief of Engineers and Commanding General, U.S. Army Corps of Engineers, Washington, D.C. (ex officio)

THE NATIONAL ACADEMIES

Advisers to the Nation on Science, Engineering, and Medicine

The **National Academy of Sciences** is a private, nonprofit, self-perpetuating society of distinguished scholars engaged in scientific and engineering research, dedicated to the furtherance of science and technology and to their use for the general welfare. On the authority of the charter granted to it by the Congress in 1863, the Academy has a mandate that requires it to advise the federal government on scientific and technical matters. Dr. Ralph J. Cicerone is president of the National Academy of Sciences.

The **National Academy of Engineering** was established in 1964, under the charter of the National Academy of Sciences, as a parallel organization of outstanding engineers. It is autonomous in its administration and in the selection of its members, sharing with the National Academy of Sciences the responsibility for advising the federal government. The National Academy of Engineering also sponsors engineering programs aimed at meeting national needs, encourages education and research, and recognizes the superior achievements of engineers. Dr. Charles M. Vest is president of the National Academy of Engineering.

The **Institute of Medicine** was established in 1970 by the National Academy of Sciences to secure the services of eminent members of appropriate professions in the examination of policy matters pertaining to the health of the public. The Institute acts under the responsibility given to the National Academy of Sciences by its congressional charter to be an adviser to the federal government and, on its own initiative, to identify issues of medical care, research, and education. Dr. Harvey V. Fineberg is president of the Institute of Medicine.

The **National Research Council** was organized by the National Academy of Sciences in 1916 to associate the broad community of science and technology with the Academy's purposes of furthering knowledge and advising the federal government. Functioning in accordance with general policies determined by the Academy, the Council has become the principal operating agency of both the National Academy of Sciences and the National Academy of Engineering in providing services to the government, the public, and the scientific and engineering communities. The Council is administered jointly by both the Academies and the Institute of Medicine. Dr. Ralph J. Cicerone and Dr. Charles M. Vest are chair and vice chair, respectively, of the National Research Council.

The **Transportation Research Board** is one of six major divisions of the National Research Council. The mission of the Transportation Research Board is to provide leadership in transportation innovation and progress through research and information exchange, conducted within a setting that is objective, interdisciplinary, and multimodal. The Board's varied activities annually engage about 7,000 engineers, scientists, and other transportation researchers and practitioners from the public and private sectors and academia, all of whom contribute their expertise in the public interest. The program is supported by state transportation departments, federal agencies including the component administrations of the U.S. Department of Transportation, and other organizations and individuals interested in the development of transportation. **www.TRB.org**

AR0073788

FOREWORD

This fifth edition of the *Highway Capacity Manual* breaks a great deal of new ground.

- It is the first *Highway Capacity Manual* to provide an **integrated multimodal approach** to the analysis and evaluation of urban streets from the points of view of automobile drivers, transit passengers, bicyclists, and pedestrians. This is the first manual to take into account the effects of cars on bicyclists and pedestrians.
- It is the first to address the proper **application of microsimulation analysis** and the evaluation of those results.
- It is the first to discuss **active traffic management** in relation to both demand and capacity.
- It is the first to include **example applications of its procedures implemented in software code and executables** to assist users and software developers in understanding the subtleties of the methodologies.
- It is also the first to provide tools, **generalized service volume tables**, to assist planners in quickly sizing future facilities.

While this edition of the *Highway Capacity Manual* has many firsts, it also builds on more than 60 years of work by many dedicated experts in the field.[1]

The *First Highway Capacity Manual* was published in 1950 as a joint venture between the Highway Research Board's Committee on Highway Capacity and the Bureau of Public Roads. That effort was led by O. K. Normann, committee chair, and William Walker, committee secretary. The manual was the first international document on the broad subject of capacity and provided definitions of key terms, a compilation of maximum observed flows, and the initial fundamentals of capacity.

The second edition was published in 1965 by the Highway Research Board and authored by the Committee on Highway Capacity. O. K. Normann led much of this effort until his untimely death in 1964. Carl C. Saal continued the work as the new committee chair with Arthur A. Carter, Jr., as secretary. The Bureau of Public Roads was again a significant contributor to the project. The 1965 manual was a significant extension of the 1950 edition and introduced the concept of level of service.

The third edition of the manual was published in 1985 by the Transportation Research Board (TRB) and authored by the Committee on Highway Capacity and Quality of Service, chaired by Carlton C. Robinson, with Charles W. Dale as secretary. Credit is also due to Robert C. Blumenthal and James H. Kell, who served as committee chairs between the publication of the 1965 and 1985 editions. The 1985 edition extended capacity analysis to additional facility types,

[1] Thanks are extended to Alan M. May for this short history of the *Highway Capacity Manual*, which was first provided in his Foreword to the 1994 edition.

AR0073789

incorporated driver perceptions into level of service and was the first to have the analysis procedures implemented on computer software.

An update to the third edition of the manual was published in 1994 with Adolf D. May as chair of the committee and Wayne K. Kittelson as secretary. The 1994 edition of the manual is noted for new procedures for the analysis of freeway ramp junctions, all-way and two-way stop-controlled intersections, and two-lane rural highways.

The fourth edition of the manual was published in 2000 with John D. Zegeer as chair of the committee and Richard C. Dowling as secretary. That manual was the first to go to a multivolume format (with one volume dedicated to concepts for policy makers) and was the first to test novel electronic formats for the manual using hypertext and narrated self-guided tutorials for some of the example problems.

The *Highway Capacity Manual* has grown over the decades, and it has long since ceased to be the product of a few highly competent experts or even that of a single committee. This edition of the *Highway Capacity Manual* has benefited from the most extensive involvement of the professional community—far surpassing that of all the previous editions. More than 200 professionals, many of them entirely new to TRB, the Committee on Highway Capacity and Quality of Service, and the manual development process itself, contributed to the year-long chapter review process, which has culminated in the publication of this fifth edition.

This edition is the first to involve other TRB committees in its development. The following committees from the Operations Section (AHB00) of the Technical Activities Council of TRB provided reviewers or comments directly on the drafts of the manual:

- AHB20, Freeway Operations;
- AHB25, Traffic Signal Systems;
- AHB35, Committee on High-Occupancy Vehicle, High Occupancy Toll, and Managed Lanes; and
- AHB45, Traffic Flow Theory and Characteristics.

The members of the Committee on Highway Capacity and Quality of Service thank these committees for their assistance and thank the chairs of the Operations Section, Daniel S. Turner and Ivan Peter M. Briglia, Jr., for their support and encouragement of the multicommittee involvement in the development of the *Highway Capacity Manual*.

We are also grateful for the support we have received from the members and staff of the Institute of Transportation Engineers (ITE). Our joint summer meetings with local ITE sections throughout the manual development process were particularly informative and productive.

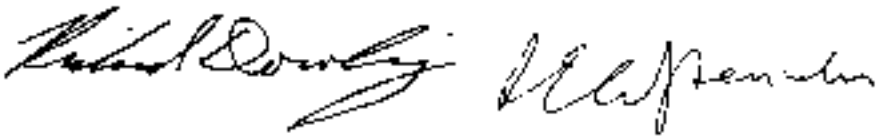
Throughout this effort, the advice and support of Richard Cunard, Engineer of Traffic and Operations of TRB, was extremely valuable in helping the committee anticipate, address, and overcome the obstacles that arise every time a major new document is published.

AR0073790

The *Highway Capacity Manual 2010* would never have become a reality without the hard work of the National Cooperative Highway Research Program (NCHRP) 3-92 panel, chaired by Barbara Ostrom, with Ray Derr as Senior Program Officer for the project. The committee thanks the NCHRP 3-92 panel, its staff, and its contractor, Kittelson & Associates, Inc. for delivering a high-quality manual that will greatly improve transportation engineering and planning practice in the years to come.

The committee invites those interested in improving the profession's understanding of capacity and quality of service analysis to contact us at www.AHB40.org and become involved.

For the Committee on Highway Capacity and Quality of Service (AHB40),



Richard G. Dowling
Committee Chair
October 1, 2010

Lily Elefteriadou
Committee Secretary

AR0073791

CONTRIBUTORS AND ACKNOWLEDGMENTS

The *Highway Capacity Manual 2010* is the result of the coordinated efforts of many individuals, groups, research organizations, and government agencies. The TRB Committee on Highway Capacity and Quality of Service is responsible for the content of the *Highway Capacity Manual*; preparation of the manual was accomplished through the efforts of the following groups and individuals:

TRB COMMITTEE ON HIGHWAY CAPACITY AND QUALITY OF SERVICE

(Members as of January 31, 2010)

Richard Dowling, *Dowling Associates, Inc.* — *Chairman*
Lily Elefteriadou, *University of Florida* — *Secretary*

8. HCM Primer
9. Glossary and Symbols

The *Highway Capacity Manual 2010* (HCM) is the fifth edition of this fundamental reference document. Like its predecessors, the HCM 2010 has been significantly revised to incorporate the latest research on highway capacity and quality of service. It has also been substantially reorganized. These changes continue the HCM's evolution, keeping the manual in step with its users' needs and present times.

The 1950 HCM (1) was the first document to quantify the concept of capacity for transportation facilities and focused almost entirely on that subject. This focus was in response to the rapid expansion of the U.S. roadway system after World War II and the need to determine lane requirements for the Interstate highway system and the roads that provided access to it. The manual was designed to be "a practical guide by which the engineer, having determined the essential facts, can design a new highway or revamp an old one with assurance that the resulting capacity will be as calculated."

The focus on design continued in the 1965 HCM (2), but the level-of-service (LOS) concept was also introduced with this edition, along with a chapter on bus transit. The HCM permitted the "determination of the capacity, service volume, or level of service which will be provided by either a new highway design, or an existing highway under specified conditions."

The 1985 HCM (3) was another significant step in the evolution of the HCM. It further refined the concept of LOS and incorporated the results of several major research projects performed since the publication of the 1965 HCM. The target audience was broadened through the addition of chapters on pedestrians and bicycles and an expansion of the transit chapter.

A substantial increase in the volume and breadth of material occurred with the publication of the HCM2000 (4). The intent of the manual was "to provide a systematic and consistent basis for assessing the capacity and level of service for elements of the surface transportation system and also for systems that involve a series or a combination of individual facilities."

The HCM 2010 has updated much new material from research projects completed since the publication of HCM2000 and has been reorganized to make its contents more accessible and understandable. The reorganization is also intended to encourage analysts and decision makers to consider all roadway users, as well as a broader range of performance measures, when they assess transportation facility performance.

Chapter 1, HCM User's Guide, is the starting point for learning how to use this edition of the HCM. This chapter presents the purpose, objectives, intended use, and target users of the HCM 2010; describes the contents of each of the four volumes that make up the HCM; summarizes the major changes that have been made to HCM2000 methodologies; and mentions some of the important companion documents to the HCM. The remainder of Volume 1 presents the fundamental information with which users should be familiar before starting to apply the manual.

AR0073805

2. HCM PURPOSE AND SCOPE

PURPOSE AND OBJECTIVES

Quality of service describes how well a transportation facility or service operates from the traveler's perspective.

The purpose of the HCM is to provide a set of methodologies and associated application procedures for evaluating the multimodal performance of highway and street facilities in terms of operational measures and two or more quality-of-service dimensions.

The objectives of the HCM are to

1. Define performance measures and their primary methods for key traffic characteristics,
2. Provide methodologies for estimating and predicting performance measures, and
3. Explain methodologies at a level of detail that allows readers to understand the factors affecting multimodal operation.

Level of service is the A–F stratification of quality of service.

The HCM 2010 presents the best available techniques at the time of publishing for determining capacity and LOS. However, it does not establish a legal standard for highway design or construction.

INTENDED USE

The HCM is intended to be used primarily for the analysis areas listed below, to the extent that they are supported by the individual analysis methodologies.

- *Levels of analysis*: operations, design, preliminary engineering, and planning.
- *Travel modes*: automobile (and other motorized vehicles), pedestrian, and bicycle, plus transit when it is part of a multimodal urban street facility.
- *Spatial coverage*: points, segments, and facilities.
- *Temporal coverage*: under undersaturated and oversaturated conditions.

TARGET USERS

The HCM is prepared for use by (a) engineers who work in the field of traffic operations or highway geometric design and (b) transportation planners who work in the field of transportation system management. To use the manual effectively and to apply its methodologies, some technical background is demanded—typically university-level training or technical work in a public agency or consulting firm.

The HCM is also useful to management personnel, educators, air quality specialists, noise specialists, elected officials, regional land use planners, and interest groups representing special users.

AR0073806

3. STRUCTURE

OVERVIEW

Since 2000, more than $5 million in funded National Cooperative Highway Research Program (NCHRP) research has partially or entirely focused on HCM methodologies. To keep the HCM at a manageable size and yet incorporate the results of this research, the HCM 2010 has been divided into four volumes.

1. Concepts,
2. Uninterrupted Flow,
3. Interrupted Flow, and
4. Applications Guide.

When the HCM2000 (4) was being developed, U.S. states were moving toward compliance with federal requirements to use metric units in the design of roadways. As a result, the HCM2000 was published in "U.S. customary" and "metric" versions. Because the federal metrication requirements were later dropped and most states returned to U.S. customary units, this edition only uses U.S. customary units. A metric conversion guide is provided later in this chapter.

The following sections describe the contents of each HCM 2010 volume.

VOLUME 1: CONCEPTS

Volume 1 covers the basic information that an analyst should be familiar with before performing capacity or quality-of-service analyses. Its chapters cover the organization of the HCM; the kinds of applications that can be performed with the HCM; modal characteristics; traffic flow, capacity, and quality of service concepts; the range of tools available to perform an analysis; guidance on interpreting and presenting analysis results; and the terms and symbols used in the HCM. Chapter 8, HCM Primer, provides an executive summary of the HCM for decision makers.

Users familiar with the HCM2000 will find that Volume 1 incorporates Part I of the HCM2000; conceptual material from HCM2000 Parts II, IV, and V; and new material developed for the 2010 edition. Volume 1 is provided in three-ring binder and electronic formats, to facilitate the addition of new conceptual materials as new research is incorporated into the HCM between major updates.

VOLUME 1: CONCEPTS
1. HCM Users Guide
2. Applications
3. Modal Characteristics
4. Traffic Flow and Capacity Concepts
5. Quality and Level of Service Concepts
6. HCM and Alternative Analysis Tools
7. Interpreting HCM and Alternative Tool Results
8. HCM Primer
9. Glossary and Symbols

Chapter 8 serves as an executive summary of the HCM for decision makers.

VOLUME 2: UNINTERRUPTED FLOW

Volume 2 contains the methodological chapters relating to uninterrupted-flow system elements. All of the material necessary in performing an analysis of one of these elements appears here: a description of the process (enough to allow an analyst to understand the steps involved (although not necessarily replicate them by hand), the scope and limitations of the methodology, specific default values, LOS thresholds, and guidance on special cases and the use of alternative tools.

The freeway chapters are presented first, arranged from the facility level down to the segment level; the chapters for multilane and two-lane highways

VOLUME 2: UNINTERRUPTED FLOW
10. Freeway Facilities
11. Basic Freeway Segments
12. Freeway Weaving Segments
13. Freeway Merge and Diverge Segments
14. Multilane Highways
15. Two-Lane Highways

Uninterrupted-flow system elements, such as freeways, have no fixed causes of delay or interruption external to the traffic stream.

AR0073807

follow. Users familiar with the HCM2000 will find that Volume 2 incorporates the Part III uninterrupted-flow chapters, along with the material from the corresponding Part II chapters (e.g., specific default values and LOS thresholds) used directly in an analysis. The Interchange Ramp Terminals chapter, which appeared with the uninterrupted-flow chapters in the HCM2000, appears with the interrupted-flow chapters (Volume 3) in the HCM 2010.

Volume 2 is provided in both three-ring binder and electronic formats to facilitate interim HCM updates as new research is performed.

VOLUME 3: INTERRUPTED FLOW
15. Urban Street Facilities
17. Urban Street Segments
18. Signalized Intersections
19. TWSC Intersections
20. AWSC Intersections
21. Roundabouts
22. Interchange Ramp Terminals
23. Off-Street Pedestrian and Bicycle Facilities

Interrupted-flow system elements, such as urban streets, have traffic control devices such as traffic signals and stop signs that periodically interrupt the traffic stream.

VOLUME 3: INTERRUPTED FLOW

Volume 3 contains all of the methodological chapters relating to interrupted-flow system elements. Its content is similar to that of the Volume 2 chapters. The facility chapter is presented first, followed by the segment chapter, the point chapters, and a chapter on off-street pedestrian and bicycle facilities.

Volume 3 incorporates the interrupted-flow chapters from the HCM2000's Part III, along with the corresponding detailed Part II material. Where applicable, pedestrian and bicycle material has been integrated throughout the Volume 3 chapters, along with public transit material specific to multimodal analyses. Users are referred to the *Transit Capacity and Quality of Service Manual* (TCQSM) (3) for transit-specific analysis procedures. The HCM2000 Unsignalized Intersections chapter has been split into three chapters in the 2010 edition, which individually cover two-way STOP-controlled intersections, all-way STOP-controlled intersections, and roundabouts. Finally, the Interchange Ramp Terminals chapter is now included with the interrupted-flow chapters.

Volume 3 is provided in both three-ring-binder and electronic formats to facilitate interim HCM updates as new research is performed.

VOLUME 4: APPLICATIONS GUIDE
Methodological Detail:
24. Concepts: Supplemental
25. Freeway Facilities: Supplemental
26. Freeway and Highway Segments: Supplemental
27. Freeway Weaving: Supplemental
28. Freeway Merges and Diverges: Supplemental
29. Urban Street Facilities: Supplemental
30. Urban Street Segments: Supplemental
31. Signalized Intersections: Supplemental
32. Stop-Controlled Intersections: Supplemental
33. Roundabouts: Supplemental
34. Interchange Ramp Terminals: Supplemental
35. Active Traffic Management
Interpretation
Case Studies
Technical Reference Library

VOLUME 4: APPLICATIONS GUIDE

Volume 4 is an electronic-only volume (www.HCM2010.org) that includes four types of content: supplemental chapters, methodological interpretations, comprehensive case studies, and a technical reference library.

The supplemental chapters include the following:

- More detailed descriptions of certain computational methodologies, written for users who seek a greater depth of understanding or plan to develop HCM implementation software;
- Example applications of alternative tools to situations not addressed by the Volume 2 or 3 chapter's methodology;
- Additional example problems and calculation results; and
- A new chapter on the impact of active traffic management techniques on freeway operations.

The methodological interpretations section will develop over time, as users apply the HCM 2010 and pose questions about particular methodologies to the Transportation Research Board (TRB) Committee on Highway Capacity and Quality of Service (AHB40). Clarifications of, interpretations of, and corrections

AR0073808

to the HCM that have been officially approved by the committee will be posted in the interpretations section of Volume 4.

Access Volume 4 at www.HCM2010.org

The comprehensive case studies illustrate how to use the HCM to perform common types of analyses. The case studies are focused on the process of applying the HCM, rather than on the details of performing calculations (which are addressed by the example problems). Case Studies 1 through 5 are derived from the web-based *HCM Applications Guidebook* (6) that was developed after the HCM2000 was published, while Case Study 6 was developed by the NCHRP 3-85 project (7).

The Technical Reference Library contains a selection of papers, technical reports, and computer documents that provide background information about the development of HCM methodologies.

COMPUTATIONAL ENGINES

Historically, all HCM methodologies have been fully documented within the manual through text, figures, and worksheets (the Freeway Facilities chapter in the HCM2000 represents the first departure from this pattern). However, in response to practitioner needs and identified HCM limitations, methodologies have continued to grow in complexity, and some have reached the point where they can no longer be feasibly documented in such a manner (for example, methodologies that require multiple iterations to reach a solution). In those cases, computational engines become an important means by which details of some of the more complex calculations can be fully described. For the most complex methodologies, the Volume 2 or 3 chapter, the Volume 4 supplemental chapter, and the computational engine together provide the most efficient and effective way of fully documenting the methodology.

HCM chapters describe, at a minimum, the process used by a given methodology. For simpler methodologies, the chapters fully describe the computational steps involved.

Supplemental chapters to Volume 4 provide calculation details for the more computationally complex methods.

Computational engines document all the calculation steps for the most complex methods, such as those requiring iterative calculations.

The TRB Committee on Highway Capacity and Quality of Service maintains computational engines for most HCM methodologies for the purposes of evaluating methodologies as they are developed, developing new example problems, identifying needed improvements, and judging the impact of proposed changes. These engines are tools for developing and documenting HCM methodologies and do not have or need the sophisticated interfaces and input data manipulation techniques that would make them suitable for use in an engineering or planning office. The engines are not generally publicly distributed but are made available on request to researchers, practitioners, software developers, students, and others who are interested in understanding the inner workings of a particular HCM methodology.

COMMERCIAL SOFTWARE

To assist users in implementing the methodologies in the manual, commercial software is available (and has been since the publication of the 1985 HCM) to perform the numerical calculations for the more computationally intensive methods. A variety of commercial software products are available that implement HCM techniques and provide sophisticated user interfaces and data manipulation tools. It is the policy of TRB not to review or endorse commercial products.

AR0073809

4. INTERNATIONAL USE

APPLICATIONS

Capacity and quality-of-service analysis have generated interest on an international scale. The HCM has been translated into several languages, and research conducted in numerous countries outside of North America has contributed to the development of HCM methodologies. HCM users are cautioned, however, that the majority of the research base, the default values, and the typical applications are from North America, particularly from the United States. Although there is considerable value in the general methods presented, their use outside of North America requires additional emphasis on calibrating the equations and the procedures to local conditions, as well as recognizing major differences in the composition of traffic in driver, pedestrian, and bicycle characteristics; and in typical geometric and control measures.

METRIC CONVERSION GUIDE

The HCM2000 (4) was produced as two editions, one using U.S. customary units and the other using metric units. Variables in the HCM2000 were subject to *hard conversion*, meaning that figures were rounded where this was reasonable. For example, a lane width of 12 ft was converted to a rounded value of 3.6 m. In comparison, a soft conversion would multiply 12 ft by a conversion factor of 0.305 m/ft, resulting in a value of 3.66 m.

As described in this chapter's Scenario section, there is no metric edition of the HCM 2010. Therefore, a soft conversion is required from U.S. customary units to metric units, so that computational engines produce the same result regardless of the measurement system used. However, in comparisons of the metric results of methodologies that have not changed from 2000 to 2010, such as multilane highways, small discrepancies may appear. The results produced by the HCM 2010 with soft conversion may be slightly different from those produced by the metric version of the HCM2000.

Exhibit 1-1 provides approximate conversion factors from U.S. customary to metric units.

5. WHAT'S NEW IN THE HCM 2010

OVERVIEW

Although the page layout of the HCM 2010 is similar to that of the HCM2000, a number of changes have been made to the manual—a result of both the extensive research that has been conducted since the HCM2000 and the feedback received from HCM2000 users.

Research Basis for the HCM 2010

Exhibit 1-2 lists the major research projects that have contributed to the HCM 2010. The impacts of these and other projects on individual HCM chapters are described later in this section.

Exhibit 1-2
Major Research Projects Contributing to the HCM 2010

Project	Project Title	Project Objective(s)
NCHRP 3-60	Capacity and Quality of Service of Interchange Ramp Terminals	Develop improved methods for capacity and quality-of-service analysis of interchange ramp terminals, for a full range of interchange types
NCHRP 3-64	*Highway Capacity Manual* Applications Guide	Develop an HCM Applications Guide that shows how to apply HCM methodologies to real-world problems and indicate when other methods may be more appropriate
NCHRP 3-65	Applying Roundabouts in the United States	Develop methods of estimating the safety and operational impacts of U.S. roundabouts and refine the design criteria used for them.
NCHRP 3-70	Multimodal Level of Service Analysis for Urban Streets	Develop a framework and enhanced methods for determining levels of service for automobile, transit, bicycle, and pedestrian modes on urban streets, in particular with respect to the interaction among the modes.
NCHRP 3-75	Analysis of Freeway Weaving Sections	Develop improved methods for capacity and LOS analysis of freeway weaving sections
NCHRP 3-79	Measuring and Predicting the Performance of Automobile Traffic on Urban Streets	Develop techniques to measure the performance of automobile traffic on urban streets for real-time applications, develop procedures to predict the performance of automobile traffic on urban streets.
NCHRP 3-80	Default Values for Capacity and Quality of Service Analyses	Determine appropriate default values for inputs to HCM analyses; develop a guide to select default values for various applications.
NCHRP 3-89	Guidance for the Use of Alternative Traffic Analysis Tools in Highway Capacity Analyses	Enhance the guidance in the HCM for the selection and use of alternative traffic analysis tools.
NCHRP 3-97	Production of the Year 2010 *Highway Capacity Manual*	Develop the 2010 edition of the HCM.
Federal Highway Administration	Evaluation of Safety, Design, and Operation of Shared-Use Paths (DTFH61-00-R-00070)	Develop an LOS estimation method for shared-use paths to assist path designers and operators in determining how wide to make new or retrofit paths and whether to separate the different types of users
Federal Highway Administration	Active Traffic Management Measures for Increasing Capacity and Improving Performance (DTFH61-05-D-00004)	Describe active traffic management techniques and available information and analysis methods for evaluating their effectiveness in increasing highway facility capacity and improving operational performance

AR0073812

Focus Groups

After the publication of the HCM2000, the TRB Committee on Highway Capacity and Quality of Service sponsored a series of focus groups at various locations around the United States to obtain feedback and to identify desired improvements for the next edition. Committee and subcommittee members also prepared an audit of the HCM in the areas of planning, design and operations, and educational needs (9). After the HCM 2010 was finished, the Institute of Transportation Engineers sponsored a web-based survey on HCM usage and desired improvements, and the NCHRP 3-92 project organized several focus groups on these topics. The feedback from these and other sources was considered when decisions were made on the format, content, and organization of the HCM 2010.

Reorganization from the HCM2000

As described in detail in this chapter's Structure section, the HCM 2010 consists of four volumes: (a) Volume 1: Concepts, (b) Volume 2: Uninterrupted Flow, (c) Volume 3: Interrupted Flow, and (d) Volume 4: Applications Guide. Material from Parts I to V of the HCM2000 has been distributed to Volumes 1 to 4 of the HCM 2010 as follows:

- *Part I: Overview* material appears in Volume 1.
- *Part II: Concepts* material appears in Volumes 2 and 3 if used directly in an analysis (e.g., default values and LOS tables) and in Volume 1 otherwise.
- *Part III: Methodologies* material appears in Volume 2 for uninterrupted-flow chapters and Volume 3 for interrupted-flow chapters. Worksheets and highly detailed descriptions of methodological steps appear in the Volume 4 chapters.
- *Part IV: Corridor and Network* material that is conceptual in nature appears in Volume 1. More detailed analytical material has been removed in favor of guidance on the use of alternative tools for corridor and areawide analyses.
- *Part V: Simulation and Other Models* material has been distributed throughout the HCM 2010. Volume 1 contains an overview of alternative tools (Chapter 6) and general guidance on comparing HCM and alternative results (Chapter 7). Specific guidance on when to consider alternative tools is presented in each chapter in Volumes 2 and 3. Selected Volume 4 chapters provide examples of applying alternative tools to situations that cannot be addressed by HCM methodologies.

Multimodal Approach

To encourage HCM users to consider all travelers on a facility when they perform analyses and make decisions, the HCM 2010 integrates material on nonmotorized and motorized modes. Thus, there are no stand-alone Pedestrian, Bicycle, and Transit chapters in this edition. Instead, users should refer to the Urban Streets chapter for analysis procedures for pedestrians, bicyclists, and transit users on urban streets, to the Signalized Intersections chapter for procedures relating to signalized intersections, and so on.

AR0073813

In recognition of the companion TCQSM (9) and of the difficulty in keeping the two manuals in synch, users are referred to the TCQSM for transit-specific capacity and quality-of-service procedures. However, transit quality of service in a multimodal context continues to be addressed in the HCM.

Traveler-Perception Models

Since the 1985 HCM, LOS has been defined in terms of measures of operational conditions within a traffic stream (1, 2). HCM methodologies have generally presented a single LOS measure per system element that can be (a) directly measured in the field, (b) perceived by travelers, and (c) affected by facility owners. However, since the publication of the HCM2000, a number of research projects have studied whether a single operational factor is sufficient to describe LOS, as well as whether nonoperational factors should also be used (10). These projects have proposed models that (a) incorporate multiple factors of traveler satisfaction and (b) set LOS thresholds based on traveler perceptions of service quality. Traveler perception models from two of these studies (11, 12) have been incorporated into the Multilane Highways, Two-Lane Highways, Urban Street Facilities, Urban Street Segments, and On-Street Pedestrian and Bicycle Facilities chapters.

Generalized Service Volume Tables

The HCM2000 provided "example service volume tables" for 10 system elements. The service volume tables were developed by using a single set of default values and were accompanied by cautionary notes that they were illustrative only. The HCM 2010 provides "generalized service volume tables" for facilities that incorporate a range of national default values. These tables can be considered for such applications as statewide performance reporting, areawide (i.e., regional) modeling, and future-year analyses as part of a long-range transportation planning process.

METHODOLOGICAL CHANGES BY SYSTEM ELEMENT

Freeway Facilities

The basic methodology is similar to the one given in the HCM2000 but incorporates the new weaving-segment analysis procedure. A significant change is the addition of LOS thresholds for freeway facilities based on density. Other changes include updates to the material on the impact of weather and work zones on freeway facility capacity, along with new information on the impact of active traffic management measures on freeway operations.

Basic Freeway Segments

The basic methodology is similar to the one given in the HCM2000. The free-flow speed prediction model has been improved, and a speed–flow curve for segments with 75 mi/h free-flow speeds has been added.

AR0073814

Freeway Weaving Segments

This chapter has been completely updated and incorporates the methodology developed by the NCHRP 3-75 project. Although the general process for analyzing weaving segments is similar to that given in the HCM2000, the HCM 2010 models are based on an up-to-date set of weaving data. The following are the two major differences in how the methodology is applied: (a) there is now a single algorithm for predicting weaving speeds and a single algorithm for predicting nonweaving speeds regardless of the weaving configuration, and (b) the LOS F threshold was changed.

Ramps and Ramp Junctions

The following revisions have been made to the HCM2000 methodology:

- Procedures have been added to check for unreasonable lane distributions that overload the left or right lane(s) (or both) of the freeway.
- A revision has been made to correct an illogical trend involving on-ramps on right-lane freeways in which density increases as the length of the acceleration lane increases.

Multilane Highways

The multilane highways automobile methodology is essentially the same as that given in the HCM2000. A methodology for calculating bicycle LOS for multilane highways has been added.

Two-Lane Highways

The following revisions have been made to the HCM2000 automobile methodology:

- The two-direction analysis has been dropped; the one-direction methodology is the only one used, with two-direction results obtained by appropriate weighted averaging of the one-direction results.
- Several key curves and tables used in one-direction analysis have been adjusted and incorporated into the chapter.

A bicycle LOS methodology for two-lane highways has been added.

Urban Street Facilities

This is a new chapter that contains guidance to help analysts determine the scope of their analysis (i.e., isolated intersection versus coordinated signal system) and the relevant travel modes (i.e., automobile, pedestrian, bicycle, transit, or a combination). The methodology section describes how to aggregate results from the segment and point levels of analysis into an overall facility assessment. Information on the impact of active traffic management measures on urban street performance has been added.

AR0073815

Urban Street Segments

This chapter has been completely rewritten. The work of the NCHRP 3-79 project has been incorporated into the chapter, providing improved methods for estimating urban street free-flow speeds and running times, along with a new method for estimating the stop rate along an urban street. In addition, the work of the NCHRP 3-70 project has been incorporated, providing a multimodal LOS methodology that can be used to evaluate trade-offs in how urban street right-of-way is allocated among the modes using the street.

Signalized Intersections

The following revisions have been made to the HCM2000 methodology:

- A new incremental queue accumulation method has been added to calculate the d_3 delay term and the Q_3 length term. It is equivalent to the HCM2000 method for the isolated case but is more flexible to accommodate nonideal cases, including coordinated arrivals and multiple green periods with differing saturation flow rates (i.e., protected-plus-permitted left turns and shoulders).
- An actuated controller operation modeling procedure has been added.
- A left-turn lane overflow check procedure has been added.
- Pedestrian and bicycle LOS methodologies relating to signalized intersections have been moved into this chapter.

Unsignalized Intersections

The HCM2000's Unsignalized Intersections chapter has been split into three chapters: two-way STOP-controlled intersections, all-way STOP-controlled intersections, and roundabouts.

Two-Way Stop-Controlled Intersections

The two-way STOP-controlled intersection methodology for the automobile mode is essentially the same as the one given in the HCM2000, except gap-acceptance parameters for six-lane streets have been added. In addition, pedestrian and bicycle LOS methodologies relating to two-way STOP-controlled intersections have been moved into this chapter.

All-Way Stop-Controlled Intersections

The all-way STOP-controlled intersection methodology is essentially the same as the one given in the HCM2000. A queue-estimation model has been added.

Roundabouts

This chapter replaces the HCM2000 roundabout content. It is based on the work of the NCHRP 3-65 project, which developed a comprehensive database of U.S. roundabout operations and new methodologies for evaluating roundabout performance. A LOS table for roundabouts has been added.

Interchange Ramp Terminals

This chapter is completely updated on the basis of the NCHRP 3-60 project.

AR0073816

Off-Street Pedestrian and Bicycle Facilities

The pedestrian path procedures are essentially the same as those of the HCM2000, but guidance is provided on how to apply the procedures to a wider variety of facility types. The bicycle path procedures, which were based on Dutch research in the HCM2000, have been updated on the basis of results of a Federal Highway Administration (FHWA) study to calibrate the Dutch model for U.S. conditions and increase the number of path user groups (e.g., inline skaters and runners) addressed by the procedures.

AR0073817

6. COMPANION DOCUMENTS

Throughout its 60 year history, the HCM has been one of the fundamental reference works used by transportation engineers and planners. However, it is but one of a number of documents that play a role in the planning, design, and operation of transportation facilities and services. The HCM's scope is to provide tools to evaluate the performance of highway and street facilities in terms of operational and quality-of-service measures. This section describes companion documents to the HCM that cover important topics outside the HCM's scope.

HIGHWAY SAFETY MANUAL

The *Highway Safety Manual* (HSM) (4) provides analytical tools and techniques for quantifying the safety effects of decisions related to planning, design, operations, and maintenance. The information in the HSM is provided to assist agencies as they integrate safety into their decision making processes. It is a nationally used resource document intended to help transportation professionals conduct safety analyses in a technically sound and consistent manner, thereby improving decisions made on the basis of safety performance.

A POLICY ON GEOMETRIC DESIGN OF HIGHWAYS AND STREETS

The American Association of State Highway and Transportation Officials' *A Policy on Geometric Design of Highways and Streets* ("Green Book") (14) provides design guidelines for roadways ranging from local streets to freeways, in both urban and rural locations. The guidelines "are intended to provide operational efficiency, comfort, safety, and convenience for the motorist" and to emphasize the need to consider other modal users of roadway facilities.

MANUAL ON UNIFORM TRAFFIC CONTROL DEVICES

FHWA's *Manual on Uniform Traffic Control Devices for Streets and Highways* (MUTCD) (15) is the national standard for traffic control devices for any street, highway, or bicycle trail open to public travel. Of particular interest to HCM users are the sections of the MUTCD pertaining to warrants for all-way stop control and traffic signal control, signing and markings to designate lanes at intersections, and associated considerations of adequate roadway capacity and less restrictive intersection treatments.

TRANSIT CAPACITY AND QUALITY OF SERVICE MANUAL

The TCQSM (6) is the transit counterpart to the HCM. The manual contains background, statistics, and graphics on the various types of public transportation, and it provides a framework for measuring transit availability, comfort, and convenience from the passenger point of view. The manual contains quantitative techniques for calculating the capacity of bus, rail, and ferry transit services and transit stops, stations, and terminals.

Types of HCM analyses users.

The Highway Capacity Manual (HCM) can be applied to transportation applications that range from the highly detailed to the highly generalized, to roadway system elements that range from individual points to an entire transportation system, to four travel modes that can be considered separately or in combination, and to several types of roadway and facility operating conditions. **Chapter 2, Applications,** introduces the wide range of potential HCM applications, all of which can be applied as stand-alone analyses or as an input to or support of a broader process.

The HCM can be applied at the *operational*, *design*, *preliminary engineering*, and *planning* analysis levels. The required input data typically remain the same at each analysis level, but the degree to which analysis inputs use default values instead of actual measured or forecast values differs. In addition, operational analysis and planning and preliminary engineering analyses final ly evaluate the level of service (LOS) that will result from a given set of inputs, whereas design analyses typically determine which facility characteristics will be needed to achieve a desired LOS.

Travel modes and roadway system elements addressed by the HCM.

The travel modes covered by the HCM are the *automobile* (including other motorized vehicles such as trucks, recreational vehicles (RVs), intercity buses, and motorcycles), *pedestrian*, and *bicycle* modes, as well as *public transit* vehicles that operate on urban streets. All of these modes operate on a variety of roadway system elements, including *points* (e.g., intersections), *segments* (e.g., lengths of roadways between intersections), *facilities* (an aggregation of points and segments into longer lengths), or *systems* (parallel freeway and arterial facilities), and at the largest geographic scales, *areas* and *systems*.

Individual methodological chapters discuss the extent to which the HCM can be used for oversaturated analyses. Chapter 6 describes alternative analysis tools that may be applied in situations in which the HCM cannot be used.

HCM methodologies are provided both for *uninterrupted-flow* facilities, which have no fixed causes of delay or interruption external to the traffic stream, and for *interrupted-flow* facilities, on which traffic control devices such as traffic signals and stop signs periodically interrupt the traffic stream. HCM analyses are applicable to *undersaturated* conditions (when demand is less than a roadway system element's capacity) and, in certain situations, to *oversaturated* conditions (when demand exceeds capacity).

Finally, measures generated by HCM methodologies can be used for more than just stand-alone traffic analyses. This chapter describes potential applications of HCM methodologies to noise, air quality, economic, and multimodal planning analyses.

AR0073823

2. LEVELS OF ANALYSIS

OVERVIEW

Any given HCM application can be analyzed at different levels of detail, depending on the purpose of the analysis and the amount of information available. The HCM defines three primary levels of analysis:

- *Operational analysis*, typically focusing on current or near-term conditions, involving detailed inputs to HCM procedures, with no or minimal use of default values;
- *Design analysis*, typically using HCM procedures to identify the required characteristics of a transportation facility that will allow it to operate at a desired LOS, with some use of default values; and
- *Planning and preliminary engineering analysis*, typically focusing on future conditions, where it is desired to evaluate a series of alternatives quickly or when specific input values to procedures are not known, requiring the extensive use of default values.

The following sections describe these analysis levels further.

OPERATIONAL ANALYSIS

Operational analyses are applications of the HCM that are generally oriented toward current or near-term conditions. They aim at providing information for decisions on whether there is a need for improvements to an existing point, segment, or facility. Occasionally, an analysis is made to determine whether a more extensive planning study is needed. Sometimes the focus is on a network, or part of one, that is approaching oversaturation or an undesirable LOS. Where, in the near term, is the facility likely to fail (or fail to meet a desired LOS threshold)? To answer this question, an estimate of the service flow rate allowable under a specified LOS is required.

For concept of LOS as described in Chapter 3, Quality and Level-of-Service Concepts

HCM analyses also help practitioners make decisions about operating conditions. Typical alternatives often involve the analysis of appropriate lane configurations, alternative traffic control devices, signal timing and phasing, spacing and location of bus stops, frequency of bus service, and addition of a managed (e.g., high-occupancy vehicle) lane or a bicycle lane. The analysis produces operational measures for a comparison of the alternatives.

Because of the immediate, short-term focus of operational analyses, it is possible to provide detailed inputs to the models. Many of the inputs may be based on field measurements of traffic, physical features, and control parameters. Generally, it is inappropriate to use default values at this level of analysis.

DESIGN ANALYSIS

Design analyses primarily apply the HCM to establish the detailed physical features that will allow a new or modified facility to operate at a desired LOS. Design projects are usually targeted for mid- to long-term implementation. Not all the physical features that a designer must determine are reflected in the HCM models. Typically, analysts using the HCM seek to determine such elements as

AR0073824

the basic number of lanes required and the need for auxiliary or turning lanes. However, an analyst can also use the HCM to establish values for elements such as lane width, steepness of grade, length of added lanes, size of pedestrian queuing areas, widths of sidewalks and walkways, and presence of bus turnouts.

The data required for design analyses are fairly detailed and are based substantially on proposed design attributes. However, the intermediate to long-term focus of the work will require use of some default values. This simplification is justified in part by the limits on the accuracy and precision of the traffic predictions with which the analyst is working.

PLANNING AND PRELIMINARY ENGINEERING ANALYSIS

Planning analyses are applications of the HCM generally directed toward broad issues such as initial problem identification (e.g., screening a large number of locations for potential operations deficiencies), long-range analyses, and statewide performance monitoring. An analyst often must estimate the future times at which the operation of the current and committed systems will fall below a desired LOS. Preliminary engineering analyses are often conducted to support planning decisions related to roadway design concept and scope, and when alternatives analyses are performed. These studies can also assess proposed systemic policies, such as lane-use control for heavy vehicles, systemwide freeway ramp metering and other intelligent transportation system applications, and the use of demand-management techniques (e.g., congestion pricing) (*1*).

Planning and preliminary engineering analyses typically involve situations in which not all of the data needed for the analysis are available. Therefore, both types of analyses frequently rely on default values for many analysis inputs. Planning analyses may default nearly all inputs—for example, through the use of generalized service volume tables. Preliminary engineering analyses will typically fall between planning and design analyses in the use of default values.

RELATIONSHIP BETWEEN ANALYSIS LEVELS AND OBJECTIVES

Each methodological chapter in Volumes 2 and 3 has one basic method adapted to facilitate each of the levels of analysis. Analysis objectives include identifying a future problem, selecting an appropriate countermeasure to an identified problem, or evaluating the postimplementation success of an action. The HCM is particularly useful when a current situation is being studied in the context of future conditions or when an entirely new element of the system is being considered for implementation. Analysts studying current conditions should make direct field measurements of the performance attributes; these direct measurements can then be applied in the same manner as predicted values to determine performance measures of interest.

AR0073825

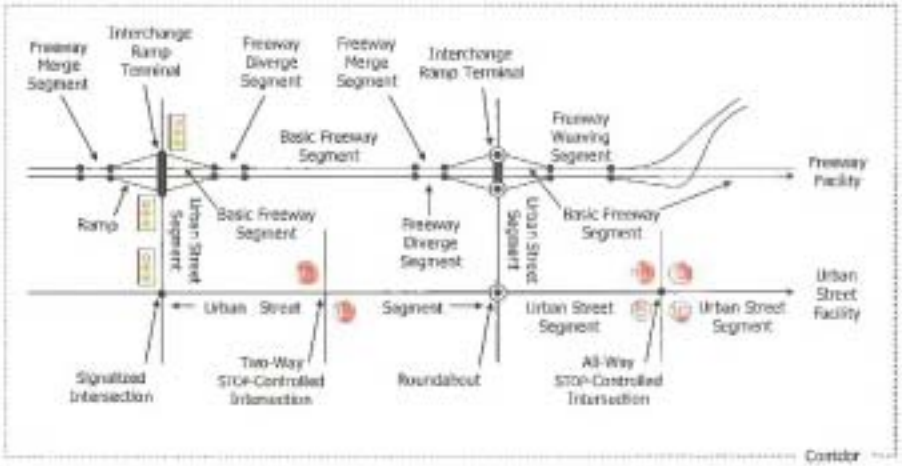
3. ROADWAY SYSTEM ELEMENTS

TYPES OF ROADWAY SYSTEM ELEMENTS

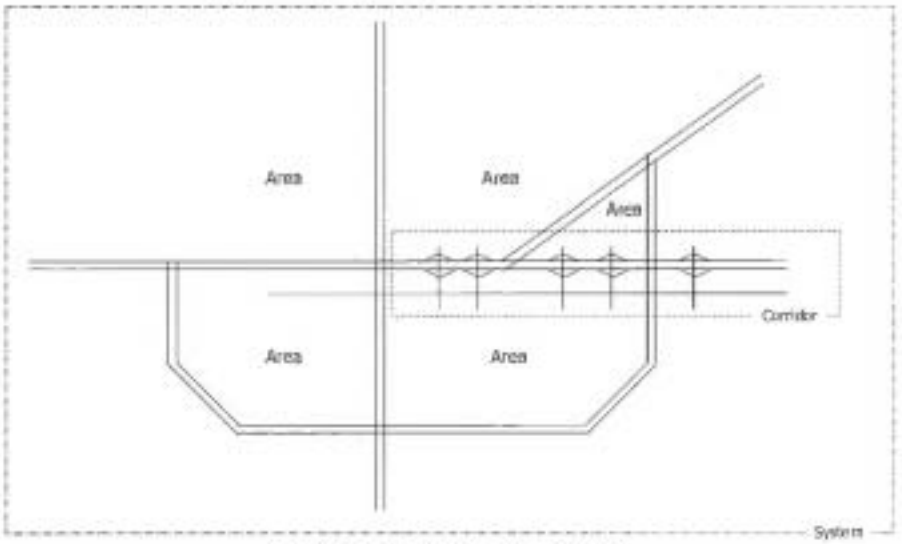
The HCM defines six main types of roadway system elements. From smallest to largest, these are points, segments, facilities, corridors, areas, and systems. The focus of the HCM is on the first three types of elements: points, segments, and facilities. Exhibit 2-1 illustrates the spatial relationships of these elements, and the following sections provide details about each system element type.

Exhibit 2-1
Illustrative Roadway System Elements

Note that a two-way STOP-controlled intersection does not normally divide the uncontrolled urban street into two segments.



(a) Points, Segments, Facilities, and Corridors



(b) Corridors, Areas, and Systems

Points

Points are places along a facility where (*a*) conflicting traffic streams cross, merge, or diverge; (*b*) a single traffic stream is regulated by a traffic control device; or (*c*) there is a significant change in the segment capacity (e.g., lane drop, lane addition, narrow bridge, significant upgrade, start or end of a ramp influence area).

AR0073826

Some points, such as interchange ramp terminals, may actually have a significant physical length associated with them, as suggested by Exhibit 2-1(a). For urban street facility analysis, points are treated as having zero length. All of the delay occurs at the point. For freeway facility analysis, points are used to define the endpoints of segments, but they have no associated performance measures or capacity, as these are calculated at the segment level.

Urban street points have a physical length but are treated as having zero length for facility analysis purposes.

Freeway points are used only to define the endpoints of segments—performance measures and capacity are not defined for them.

Segments

A segment is the length of roadway between two points. Traffic volumes and physical characteristics generally remain the same over the length of a segment, although small variations may occur (e.g., changes in traffic volumes on a segment resulting from a few volume driveways). Segments may or may not be directional. The HCM defines basic freeway segments, freeway weaving segments, freeway merge and diverge segments, and urban street segments.

Facilities

Facilities are lengths of roadways, bicycle paths, and pedestrian walkways composed of a connected series of points and segments. Facilities may or may not be directional and are defined by two endpoints. The HCM defines freeway facilities, multilane highway facilities, two-lane highway facilities, urban street facilities, and pedestrian and bicycle facilities.

The types of facilities addressed by the HCM are described in Chapter 3, Modal Characteristics.

Corridors

Corridors are generally a set of parallel transportation facilities designed to move people between two locations. For example, a corridor may consist of a freeway facility and one or more parallel urban street facilities. There may also be rail or bus transit service on the freeway, the urban streets, or both, and transit service could be provided within a separate, parallel right-of-way. Pedestrian or bicycle facilities may also be present within the corridor, as designated portions of roadways and as exclusive, parallel facilities.

Areas

Areas consist of an interconnected set of transportation facilities serving movements within a specified geographic space, as well as movements to and from adjoining areas. The primary factor distinguishing areas from corridors is that the facilities within an area need not be parallel to each other. Area boundaries can be set by significant transportation facilities, political boundaries, or topographic features such as ridgelines or major bodies of water.

Systems

Systems are composed of all the transportation facilities and modes within a particular region. A large metropolitan area typically has multiple corridors passing through it, which divide the system into a number of smaller areas. Each area contains a number of facilities, which, in turn, are composed of a series of points and segments. Systems can also be divided into modal subsystems (e.g., the roadway subsystem, the transit subsystem) as well as subsystems composed of specific roadway elements (e.g., the freeway subsystem, the urban street subsystem).

AR0073827

ANALYSIS OF INDIVIDUAL SYSTEM ELEMENTS

The HCM provides tools to help analysts estimate performance measures for individual elements of a multimodal transportation system, as well as guidance on combining those elements to evaluate larger portions of the system. Exhibit 2-2 tabulates the various system elements for which the HCM provides analysis methodologies in Volumes 2 and 3, the service measure(s) used to determine LOS for each mode operating on each system element, and the HCM performance measure that can be used to aggregate results to a system level. Some combinations of system elements and travel modes combine several performance measures into a single traveler perception model that is used to generate a LOS score. The components of each model are listed in Exhibit 2-3.

Exhibit 2-2
HCM Service Measures by System Element and Mode

System Element	HCM Chapter	Service Measure(s)				Systems Analysis Measure
		Automobile	Pedestrian	Bicycle	Transit	
Freeway facility	10	Density	--	--		Speed
Basic freeway segment	11	Density	--	--	--	Speed
Freeway weaving segment	12	Density	--	--	--	Speed
Freeway merge and diverge segments	13	Density		--		Speed

Two-way stop	19	Delay	Delay	--	--	Delay
All-way stop	20	Delay				Delay
Roundabout	21	Delay	--	--	--	Delay
Interchange ramp terminal	22	Delay	--	--	--	Delay
Off-street pedestrian–bicycle facility	23	--	Space, events[2]	LOS score[1]	--	Speed

Notes: [1] See Exhibit 2-3 for the LOS score components.
[2] Events are counts of pedestrians and bicyclists.

Exhibit 2-3
Components of Traveler Perception Models Used in the HCM

The automobile traveler perception model for urban street segments and facilities is not used to determine LOS, but it is included to facilitate multimodal analysis.

System Element	HCM Chapter	Mode	Model Components
Multilane and two-lane highways	14, 15	Bicycle	Pavement quality, perceived separation from motor vehicles, motor vehicle volume and speed
Urban street facility	16	Automobile	Weighted average of segment automobile LOS scores
		Pedestrian	Urban street segment and signalized intersection pedestrian LOS scores, midblock crossing difficulty
		Bicycle	Urban street segment and signalized intersection bicycle LOS scores, driveway conflicts
		Transit	Weighted average of segment transit LOS scores
Urban street segment	17	Automobile	Stops per mile, effective green time per cycle
		Pedestrian	Pedestrian density, sidewalk width, perceived separation from motor vehicles, motor vehicle volume and speed
		Bicycle	Perceived separation from motor vehicles, pavement quality, motor vehicle volume and speed
		Transit	Service frequency, perceived speed, pedestrian LOS
Signalized intersection	18	Pedestrian	Street crossing delay, pedestrian exposure to turning vehicle conflicts, crossing distance
		Bicycle	Perceived separation from motor vehicles, crossing distance
Off-street pedestrian–bicycle facility	23	Bicycle	Average meetings/minute, active passing route, path width, centerline presence, delayed passing

AR0073828

ASSESSMENT OF MULTIPLE FACILITIES

The analysis of a transportation system starts with estimates of delay at the point and segment level. Point delays arise from the effects of traffic control devices such as traffic signals and stop signs. Segment delays combine the point delay incurred at the end of the segment with other delays incurred within the segment. Examples of the latter include delays caused by midblock turning activity into driveways, parking activity, and midblock pedestrian crossings. The HCM estimates segment speed instead of segment delay; however, segment speed can be converted into segment delay by using Equation 2-1.

$$D_i = AVO_i \times d_i \left(\frac{L_i}{S_i} - \frac{L_i}{S_{fi}} \right) \qquad \text{Equation 2-1}$$

where

D_i = person-hours of delay on segment i,

AVO_i = average vehicle occupancy on segment i (passengers/vehicle),

d_i = vehicle demand on segment i (vehicles),

L_i = length of segment i (mi),

S_i = average vehicle speed on segment i (mi/h), and

S_{fi} = free-flow speed of segment i (mi/h).

Segment delays are added together to obtain facility estimates, and the sum of the facility estimates yields subsystem estimates. Mean delays for each subsystem are then computed by dividing the total person-hours of delay by the total number of trips on the subsystem. Subsystem estimates of delay can be combined into total system estimates, but typically the results for each subsystem are reported separately.

Normally, only the segments that constitute the collector and arterial system are used to estimate system delay.

SYSTEM PERFORMANCE MEASUREMENT

System performance must be measured in more than one dimension. When a single intersection is analyzed, it may suffice to compute only the peak period delay; however, when a system is analyzed, the geographic extent, the duration of delay, and any shifts in demand among facilities and modes must also be considered (2).

An increase in congestion on one system element may result in a shift of demand to other system elements. Therefore, estimating system delay or an alternative process, such as bridging, can be used to estimate the delay resulting from a given demand, but not the demand resulting from a given delay.

System performance can be measured in the following dimensions:

Dimensions of system performance

- *Quantity of service*—the number of person-miles and person-hours provided by the system;
- *Intensity of congestion*—the amount of congestion experienced by users of the system;
- *Duration of congestion*—the number of hours that congestion persists;
- *Extent of congestion*—the physical length of the congested system;
- *Variability*—the day-to-day variation in congestion; and
- *Accessibility*—the percentage of the populace able to complete a selected trip within a specified time.

AR0073829

Quantity of Service

Quantity of service measures the utilization of the transportation system in terms of the number of people using the system, the distance they travel (person-miles of travel, PMT), and the time they require to travel (person-hours of travel, PHT). Dividing the PMT by the PHT gives the mean trip speed in the system.

Intensity of Congestion

The intensity of congestion can be measured by using total person-hours of delay and mean trip speed. Other metrics, such as mean delay per person-trip, can also be used. In planning and preliminary engineering applications, intensity of congestion is sometimes measured in terms of volume-to-capacity ratio or demand-to-capacity ratio.

Duration of Congestion

A segment is congested if the demand exceeds the segment's discharge capacity

The duration of congestion is measured in terms of the maximum amount of time that congestion occurs anywhere in the system. A segment is congested if the demand exceeds the segment's discharge capacity. Transit subsystem congestion can occur either when the passenger demand exceeds the capacity of the transit vehicles or when the need to move transit vehicles exceeds the vehicular capacity of the transit facility.

Extent of Congestion

The extent of congestion may be expressed in terms of the directional miles of facilities congested or—more meaningfully for the public—in terms of the maximum percentage of system miles congested at any one time.

Variability

Ideally, variability should be measured in terms of either (a) the probability of occurrence of, or (b) a confidence interval for, other aspects of congestion (intensity, duration, and extent). However, the state of the practice does not yet facilitate such a calculation. Instead, a measure of the sensitivity of the results to changes in the demand can be substituted until better methods for estimating variability become available. Various levels of demand are tested (such as a 5% increase or a 5% decrease), and the resulting effects on the intensity, duration, and extent of congestion are noted in terms of a percentage increase or decrease in their values. The sensitivity can be expressed in terms of elasticity by dividing the percentage change in output by the percentage change in demand. An elasticity greater than 1.0 means that the estimated congestion measure is highly sensitive to changes in demand.

Accessibility

Accessibility examines the effectiveness of the system from a perspective other than mobility. Accessibility can be expressed in terms of the percentage of trips (or persons) able to accomplish a certain goal—such as going from home to work—within a targeted travel time. Accessibility can also be defined in terms of a traveler's ability to get to and use a particular modal subsystem, such as transit. This definition is closer to the Americans with Disabilities Act's use of the term.

AR0073830

4. TRAVEL MODES

This section introduces the four major travel modes addressed by the HCM: automobile, pedestrian, bicycle, and transit. Chapter 3 provides details about the characteristics of each mode that are important for HCM analyses.

AUTOMOBILE

The automobile mode includes all motorized vehicles except transit vehicles.

The automobile mode includes all motor vehicle traffic using a roadway except transit vehicles. Thus, trucks, RVs, motorcycles, and tour buses are all considered members of the automobile mode for HCM analyses purposes. Certain vehicle types (e.g., trucks and RVs) have operating characteristics different from those of private automobiles; these characteristics are taken into account by HCM methodologies where needed. The HCM's LOS thresholds for the automobile mode are based on the perspective of automobile drivers and passengers. Therefore, the automobile LOS measures may not necessarily reflect the perspective of drivers of other types of motorized vehicles, especially trucks.

PEDESTRIAN

The pedestrian mode consists of travelers along a roadway or pedestrian facility making a journey (or at least part of their journey) on foot. Pedestrians walk at different speeds, depending on their age, their ability, and environmental characteristics (e.g., grades and climate); HCM procedures generally account for this variability. Sidewalks and pathways may be used by more than just foot-based traffic—for example, inline skaters and persons in wheelchairs—but the HCM's LOS thresholds reflect the perspective of persons making a walking journey.

BICYCLE

The bicycle mode consists of travelers on a roadway or pathway who are using a nonmotorized bicycle for their trip. Bicycle LOS thresholds reflect their perspective. Mopeds and motorized scooters are not considered bicycles for HCM analysis purposes.

TRANSIT

The only-vehicle (OVISM) passenger capacity and speed estimation procedures for transit vehicles are additional LOS measures for transit passengers.

Urban roadways are often shared with public transit buses and, occasionally, with rail transit vehicles such as streetcars and light rail vehicles. Previous editions of the HCM have provided relatively extensive coverage of the transit mode. However, now that two editions of a companion, *Transit Capacity and Quality of Service Manual* (TCQSM) (3) have been published, the HCM now addresses the transit mode only with respect to multimodal analyses of urban streets. The HCM's LOS measure for transit on urban streets reflects the perspective of transit users—both those already on transit vehicles operating on the street and those waiting for transit vehicles at stops or stations along the street.

AR0073831

5. OPERATING CONDITIONS

UNINTERRUPTED FLOW

Uninterrupted-flow facilities have no fixed causes of delay or interruption external to the traffic stream. Volume 2 of the HCM provides analysis methodologies for uninterrupted-flow facilities.

Freeways and their components operate under the purest form of uninterrupted flow. Not only are there no fixed interruptions to traffic flow, but access is controlled and limited to ramp locations. Multilane highways and two-lane highways can also operate under uninterrupted flow in long segments between points of fixed interruption. On multilane and two-lane highways, it is often necessary to examine points of fixed interruption (e.g., traffic signals) as well as uninterrupted-flow segments.

The traffic stream on uninterrupted-flow facilities is the result of individual vehicles interacting with each other and the facility's geometric characteristics. The pattern of flow is generally controlled only by the characteristics of the land uses that generate traffic that use the facility, although freeway management and operations strategies—such as ramp metering, freeway auxiliary lanes, truck lane restrictions, variable speed limits, and incident detection and clearance—can also influence traffic flow. Operations can also be affected by environmental conditions, such as weather or lighting, by pavement conditions, and by the occurrence of traffic incidents (*4*, *5*).

"Uninterrupted flow" describes the type of facility, not the quality of the traffic flow at any given time. A freeway experiencing extreme congestion, for example, is still an uninterrupted-flow facility because the causes of congestion are internal.

INTERRUPTED FLOW

Interrupted-flow facilities have fixed causes of periodic delay or interruption to the traffic stream, such as traffic signals and STOP signs. Urban streets are the most common form of this kind of facility. Exclusive pedestrian and bicycle facilities are also treated as interrupted flow, since they may occasionally intersect other streets at locations where pedestrians and bicyclists do not automatically receive the right-of-way. Volume 3 of the HCM provides analysis methodologies for interrupted-flow facilities.

The traffic flow patterns on an interrupted-flow facility are the result not only of vehicle interactions and the facility's geometric characteristics but also of the traffic control used at intersections and the frequency of access points to the facility. Traffic signals, for example, allow designated movements to occur only during certain portions of the signal cycle (and, therefore, only during certain portions of an hour). This control creates two significant outcomes. First, time becomes a factor affecting flow and capacity because the facility is not available for continuous use. Second, the traffic flow pattern is dictated by the type of control used. For instance, traffic signals create platoons of vehicles that travel along the facility as a group, with significant gaps between one platoon and the

AR0073832

next. In contrast, all-way stop-controlled intersections and roundabouts discharge vehicles more randomly, creating small (but not necessarily usable) gaps in traffic at downstream locations (4, 6).

Platoons created by a traffic signal tend to disperse as they become more distant from the intersection. Many factors influence how quickly a platoon disperses, including the running speed and the amount of traffic that enters and leaves the facility between signalized intersections. In general, traffic signal spacing greater than 2 mi is thought to be sufficient for allowing uninterrupted flow to exist at some point between the signals. In contrast, on two-lane roadways downstream of a stop-controlled intersection or roundabout, platoons may redevelop as faster vehicles catch up to slower-moving vehicles, although this effect is again dependent on the amount of driveway traffic entering and leaving the roadway (4, 5).

UNDERSATURATED FLOW

Traffic flow during the analysis period is specified as "undersaturated" when the following conditions are satisfied: (*a*) the arrival flow rate is lower than the capacity of a point or segment, (*b*) no residual queue remains from a prior breakdown of the facility, and (*c*) traffic flow is unaffected by downstream conditions.

free-flow speed: the average speed of traffic on a segment at volume and density approach zero.

Uninterrupted-flow facilities operating in a state of undersaturated flow will typically have travel speeds within 10% to 20% of the facility's free-flow speed, even at high flow rates, assuming base conditions (e.g., level grades, standard lane widths). Furthermore, no queues would be expected to develop on the facility.

On interrupted-flow facilities, queues form as a natural consequence of the interruptions to traffic flow created by traffic signals and stop and yield signs. Therefore, travel speeds are typically 30% to 60% below the facility's free-flow speed in undersaturated conditions. Incremental cycle failures—where a vehicle has to wait through more than one green phase to be served—may occur at traffic signals under moderate- to high-volume conditions as a result of natural variations in the cycle-to-cycle arrival and service rate. Similarly, stop- and yield-controlled approaches may experience short periods of significant queue buildup. However, as long as all of the demand on an intersection approach is served within a 15-min analysis period, including any residual demand from the prior period, the approach is considered to be undersaturated.

OVERSATURATED FLOW

Traffic flow during an analysis period is characterized as "oversaturated" when any of the following conditions is satisfied: (*a*) the arrival flow rate exceeds the capacity of a point or segment, (*b*) a queue created from a prior breakdown at a facility has not yet dissipated, or (*c*) traffic flow is affected by downstream conditions.

On uninterrupted-flow facilities, oversaturated conditions result from a bottleneck on the facility. During periods of oversaturation, queues form and extend backward from the bottleneck point. Traffic speeds and flows drop

AR0073833

significantly as a result of turbulence, and they can vary considerably, depending on the severity of the bottleneck. Freeway queues differ from queues at undersaturated signalized intersections in that they are not static or "standing." On freeways, vehicles move slowly through a queue, with periods of stopping and movement. Even after the demand at the back of the queue drops, it takes some time for the queue to dissipate because vehicles discharge from the queue at a slower rate than they do under free-flow conditions. Oversaturated conditions persist within the queue until the queue dissipates after a period of time during which demand flows are less than the capacity of the bottleneck, allowing the queue to discharge completely.

On uninterrupted-flow facilities, oversaturated conditions generate a queue that grows backward from the intersection at a rate faster than can be processed by the intersection over the analysis period. Oversaturated conditions persist after demand drops below capacity until the residual queue (i.e., the queue over and above what would be created by the intersection's traffic control) has dissipated. A queue generated by an oversaturated unsignalized intersection dissipates more gradually than is typically possible at a signalized intersection.

If an intersection approach or ramp meter cannot accommodate all of its demand, queues may back into upstream intersections, adversely affecting their performance. Similarly, if an interchange ramp terminal cannot accommodate all of its demand, queues may back onto the freeway, adversely affecting its performance.

QUEUE DISCHARGE FLOW

A third type of flow, queue discharge flow, is particularly relevant for uninterrupted-flow facilities. Queue discharge flow represents traffic flow that has just passed through a bottleneck and, in the absence of another bottleneck downstream, is accelerating back to the facility's free-flow speed. Queue discharge flow is characterized by relatively stable flow as long as the effects of another bottleneck downstream are not present.

On freeways, this flow type is generally defined within a narrow range of 2,200 to 2,300 passenger cars per hour per lane, with speeds typically ranging from 35 mi/h up to the free flow speed of the freeway segment. Lower speeds are typically observed just downstream of the bottleneck. Depending on horizontal and vertical alignments, queue discharge flow usually accelerates back to the facility's free-flow speed within 0.5 to 1 mi downstream of the bottleneck. Studies suggest that the queue discharge flow rate from the bottleneck is lower than the maximum flows observed before breakdown.

Because uninterrupted-flow facilities naturally operate from queue-discharge conditions, the queue discharge flow on these facilities is equal to the saturation flow rate.

Chapter 5, Traffic Flow and Capacity Concepts, provides details about the characteristics of traffic flow during undersaturated, oversaturated, and queue discharge conditions.

AR0073834

6. HCM ANALYSIS AS PART OF A BROADER PROCESS

Since its first edition in 1950, the HCM has provided transportation analysts with the tools to estimate traffic operational measures such as speed, density, and delay. It also has provided insights and specific tools for estimating the effects of various traffic, roadway, and other conditions on the capacity of facilities. Over time, the calculated values from the HCM have increasingly been used in other transportation work. The practice of using estimated or calculated values from HCM work as the foundation for estimating user costs and benefits in terms of monetary value and environmental changes (especially air and noise) is particularly pronounced in transportation priority programs and in the justification of projects. This section provides examples of how HCM outputs can be used as inputs to other types of analyses.

NOISE ANALYSIS

At the time this chapter was written, federal regulations specifying noise abatement criteria stated that "in predicting noise levels and assessing noise impacts, traffic characteristics which will yield the worst hourly traffic noise impact on a regular basis for the design year shall be used" [23 CFR 772.17(b)]. The "worst hour" is usually taken to mean the busiest hour, which does not necessarily coincide with the busiest hour, since vehicular noise levels are directly related to speed. Traffic conditions in which large trucks are a high duty peak and in which LOS E conditions exist typically represent the busiest hour (7).

AIR QUALITY ANALYSIS

The 1990 Clean Air Act Amendments required state and local agencies to develop accurate emission inventories as an integral part of their air quality management and transportation planning responsibilities. Vehicular emissions are a significant contributor to poor air quality; therefore, the U.S. Environmental Protection Agency (EPA) has developed analysis procedures and tools for estimating emissions from mobile sources such as motorized vehicles. One input into the emissions model is average vehicle speed, which can be entered at the link (i.e., length between successive ramps) level, if desired. EPA's model has been found to be sensitive to average vehicle speed (i.e., a 20% change in average vehicle speed resulted in a greater than 20% change in the emissions estimates), implying that accurate speed inputs are a requirement for accurate emissions estimates. The HCM is a tool recommended by EPA for generating speed estimates on freeways and arterials and collectors (8, 9).

ECONOMIC ANALYSIS

The economic analysis of transportation improvements also lends itself to a large extent on information generated from the HCM. Road user benefits are directly related to reductions in travel time and delay, which results determined from construction of roadway improvements (e.g., addition of lanes, installation

AR0073835

of traffic signals) and increases in travel time and delay. The following excerpt (11, p. 3-2) indicates the degree to which such analyses depend on the HCM.

> *The HCM provides many tools and procedures to assist in the calculation of system levels of performance and the determination of system deficiencies, evaluation of effects of roadway modifications on the operational level of a highway or street system, evaluation of the benefits and costs of highways and transit using the HCM. The most accurate rendering of the effects of mobility and access on quality of service is through the use of the HCM's calculation procedures.*

MULTIMODAL PLANNING ANALYSIS

An increasing number of jurisdictions are taking an integrated approach to multimodal transportation planning. That is, rather than simply developing plans for the automobile, transit, and pedestrian and bicycle modes in isolation, these jurisdictions are evaluating trade-offs among the modes as part of their transportation planning and decision making. This edition of the HCM is designed to support those efforts. For example, Chapter 16, Urban Street Facilities, presents an integrated, multimodal set of LOS measures for urban streets. The other uninterrupted-flow chapters in Volume 3 also integrate pedestrian and bicycle measures, to the extent that research is available to support those measures.

SYSTEM PERFORMANCE MEASUREMENT

State and federal governments use HCM procedures in reporting transportation system performance. For example, the Federal Highway Administration's Highway Performance Monitoring System uses HCM procedures to estimate the capacity of highway sections and to determine volumes to service flow rates (12). Florida uses HCM procedures to estimate speeds on the state highway system as part of its mobility performance measures reporting.

SUMMARY

In summary, almost all economic analyses and all air and noise environmental analyses rely directly on one or more measures estimated or produced with HCM calculations. Exhibit 2-4 lists the automobile-based performance measures from this manual that are applicable to environmental or economic analyses.

Roadways serve users of many different modes including pedestrians, bicyclists, and transit passengers. The roadway right of way is allocated among the modes through the provision of facilities that ideally serve each mode's needs. However, in many urban situations, the right-of-way is constrained by adjacent land development, causing transportation engineers and planners to consider trade-offs in how to allocate the right-of-way. Interactions among the modes that result from different right-of-way allocations are important to consider in analyzing a roadway, and the *Highway Capacity Manual* (HCM) provides tools for assessing these interactions. Local policies and design standards relating to roadway functional classifications are other sources of guidance on the allocation of right-of-way, safety and operational concerns should also be addressed.

Chapter 3. Modal Characteristics, introduces some basic characteristics of the four major modes addressed by the HCM. The following characteristics are considered in this chapter for each mode:

- Factors that contribute to a traveler's experience during a trip,
- Observed seasonal and daily variations in travel demand,
- Types of transportation facilities employed by a given mode,
- Notable capacity and volume observations, and
- Descriptions of the interactions that occur between modes.

Chapters 4 and 5 continue the discussion of multimodal performance. Chapter 4 discusses flow and capacity concepts and provides operational performance measures for each mode. Chapter 5 discusses quality and level of service (LOS) concepts and introduces the measures of effectiveness for each mode that the HCM uses to assess transportation facilities from a traveler point of view.

AR0073841

2. AUTOMOBILE MODE

VEHICLE AND HUMAN FACTORS

Three major elements affect driving: the vehicle, the roadway environment, and the driver. This section identifies vehicle and driver characteristics and how they are affected by the roadway's environment and physical properties.

Motor Vehicle Characteristics

Characteristics of various motorized roadway users

This section provides a summary of the operating characteristics of motor vehicles that should be considered when a facility is analyzed. The major considerations are vehicle types and dimensions, turning radii and off-tracking, resistance to motion, power requirements, acceleration performance, and deceleration performance. Motor vehicles include passenger cars, trucks, vans, buses, recreational vehicles, and motorcycles. All of these vehicles have unique weight, length, size, and operational characteristics.

Vehicle acceleration and deceleration rates are factors that must be considered in designing traffic signal timing, computing sight distance and travel time, and estimating how normal traffic flow resumes after a breakdown. Passenger cars accelerate after a stop at a rate ranging between 7.5 and 9 ft/s². Trucks, however, accelerate from a stop at rates ranging from 0.7 to 3 ft/s². Maximum passenger car deceleration rates range between 10 and 25 ft/s², depending on road surface and tire conditions, with deceleration rates of 10 ft/s² or less considered reasonably comfortable for passenger car occupants (1). Typical truck deceleration rates are 6.5 ft/s² or lower (2).

Driver Characteristics

Driving is a complex task involving a variety of skills. The most important skills are taking in and processing information and making quick decisions on the basis of this information. Driver tasks are grouped into three main categories: control, guidance, and navigation. Control involves the driver's interaction with the vehicle in terms of speed and direction (accelerating, braking, and steering). Guidance refers to maintaining a safe path and keeping the vehicle in the proper lane. Navigation means planning and executing a trip.

The way in which drivers perceive and process information is important. About 90% of information is presented to drivers visually. The speed at which drivers process information is a significant component affecting their successful use of the information. One parameter used to quantify the speed at which drivers process information is perception–reaction time, which represents how quickly drivers can respond to an emergency situation. Another parameter—sight distance—is directly associated with reaction time. There are three types of sight distance: stopping, passing, and decision. Sight distance is a parameter that helps determine appropriate geometric features of transportation facilities. Acceptance of gaps in traffic streams is associated with driver perception and influences the capacity and delay of movements at unsignalized intersections.

AR0073842

factors such as nighttime driving, fatigue, driving under the influence of alcohol and drugs, the age and health of drivers, and police enforcement also contribute to driver behavior on a transportation facility. All these factors can affect the operational parameters of speed, delay, and density. However, unless otherwise specified, the HCM assumes base conditions of daylight, dry pavement, typical drivers, and so forth.

Base conditions are discussed generally in Chapter 4 and specifically in chapters on volumes 2 and 3.

VARIATIONS IN DEMAND

The traffic volume counted at a given location on a given day is not necessarily reflective of the amount of traffic (a) that would be counted on another day or (b) that would be counted if an upstream bottleneck was removed. Traffic demand varies seasonally, by day of the week (e.g., weekdays versus weekends), and by hour of the day, as trip purposes and the number of persons desiring to travel varies. Bottlenecks—locations where the capacity provided is insufficient to meet the demand during a 15-min or hourly period—constrain the observed volume to the portion of the demand that can be served by the bottleneck. Because traffic counts only provide the portion of the demand that was served, the actual demand can be difficult to identify.

Demand relates to the number of vehicles that would like to be served by a roadway element, while volume relates to the number that can actually be served.

The following sections discuss monthly, daily, and hourly variations in traffic demand. Analysts need to account for these types of variations to ensure that the peak hour demand volumes used in an HCM analysis are reflective of conditions on peak days of the year. Failure to account for these variations can result in an analysis that reflects peak conditions on the days counts were made, but not peak conditions over the course of the year. For example, a highway serving a beach resort area may be virtually unused during much of the year but become oversaturated during the peak summer periods.

Selective peaks in traffic demand must also be considered, particularly on recreational corridors.

Chapter 4, Traffic Flow and Capacity Concepts, discusses subhourly variations in demand. It is possible for a roadway's capacity to be greater than its hourly demand, yet traffic flow may still break down if the flow rate within the hour exceeds the roadway's capacity. The effects of a breakdown can extend far beyond the time during which demand exceeded capacity and may take several hours to dissipate.

A highway that is rarely able to handle a peak hour demand may be subject to breakdown if flow rates within the peak hour exceed capacity—a topic of Chapter 4.

The data shown in the exhibits in this section represent typical observations that can be made. The patterns illustrated, however, vary in response to local travel habits and environments, and these examples should not be used as a substitute for locally obtained data.

Data shown in these graphs represent typical observations but should not be used as a substitute for local data.

Seasonal and Monthly Variations

Seasonal fluctuations in traffic demand reflect the social and economic activity of the area served by the highway. Exhibit 3-1 shows monthly patterns observed in Oregon and Washington. The highway depicted in Exhibit 3-1(a) serves national forestland with both winter and summer recreational activity. The highway depicted in Exhibit 3-1(b) is a rural route serving intercity traffic. Two significant characteristics are apparent from this data set:

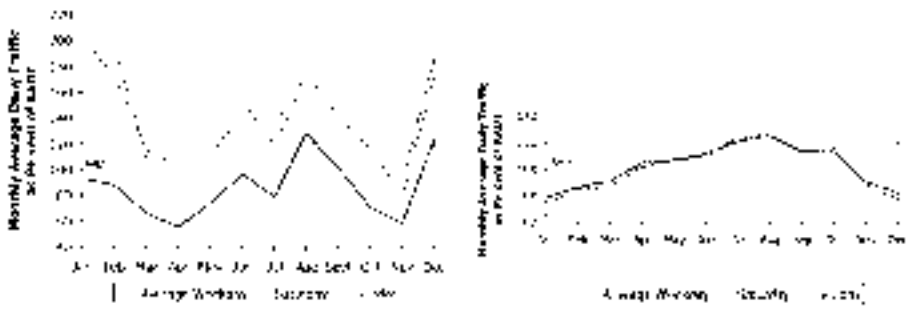
AR0073843

- The range of variation in traffic demand over the course of a year is more severe on rural routes primarily serving recreational traffic than on rural routes primarily serving intercity traffic; and
- Traffic patterns vary more severely by month on recreational routes.

Exhibit 3-1
Examples of Monthly Traffic Volume Variations for a Highway

Monthly volume variations for routes with recreational traffic show much higher seasonal peaking than do routes with predominantly intercity traffic.

The average daily traffic, averaged over a full year is referred to as the annual average daily traffic, or AADT, and is often used in forecasting and planning.



(a) Routes with Significant Recreational Traffic (b) Routes with Significant Intercity Traffic

Note: (a) Highway 35 north of Parkdale, Oregon; (b) US-97 north of Merrill, Oregon, used in for
Source: (a) Oregon DOT, 2006; (b) Washington State DOT, 2007.

These and other similar observations lead to the conclusion that recreational- and business-oriented travel generally follow fairly uniform patterns, while recreational traffic creates the greatest variation in demand patterns.

The data for Exhibit 3-2 were collected on the same Interstate route. One segment is within 1 mi of the central business district of a large metropolitan area. The other segment is within 75 mi of the first but serves a combination of recreational and intercity travel. This exhibit illustrates that monthly variations in volume are more severe on rural routes than on urban routes. The wide variation in seasonal patterns for the two segments underscores the effect of trip purpose and may also reflect capacity restrictions on the urban section.

Exhibit 3-2
Examples of Monthly Traffic Volume Variations for the Same Interstate Highway (Rural and Urban Segments)

Monthly volume variations for rural segments of Interstate highways show much higher seasonal peaking than for urban segments of the same highway. This may reflect both recreational and agricultural traffic impacts.

AR0073844

Daily Variations

Time of peak demand will vary according to highway type.

Demand variations by day of the week are also related to the type of highway. Exhibit 3-3 shows that weekend volumes are lower than weekday volumes for highways serving predominantly business travel, such as urban freeways. In comparison, peak traffic occurs on weekends on main rural and recreational highways. Furthermore, the magnitude of daily variation is highest for recreational access routes and lowest for urban commuter routes.

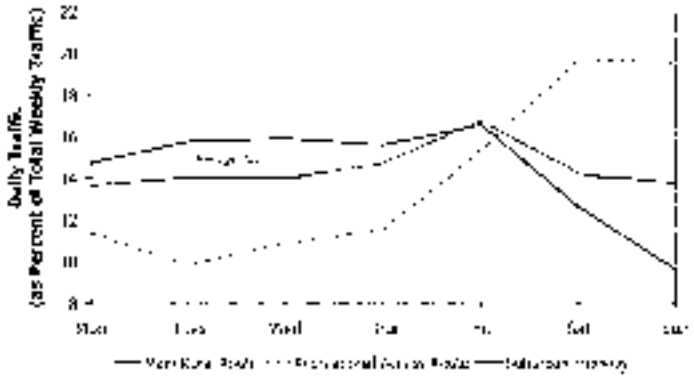

Exhibit 3-3
Examples of Daily Traffic Variation by Type of Route

Daily volume variations through the week show higher weekday volumes and lower weekend volumes for routes primarily serving commuter and business trips, but the opposite for segments serving recreational traffic. Fridays are typically the peak weekday.

Notes: Suburban Freeway, I-132 in Portland, Washington; Mountain Route, US 12 Southeast of Yakima, Washington; Intermediate Access Route, Highway 35 south of Parkdale, Oregon.
Source: Washington State DOT, 2007; and Oregon DOT, 2007.

Exhibit 3-4 shows the variation in traffic by vehicle type for the shoulder lane of an urban freeway. Although the values shown in Exhibit 3-3 and Exhibit 3-4 are typical of patterns that may be observed, they should not be used as a substitute for local studies and analyses.

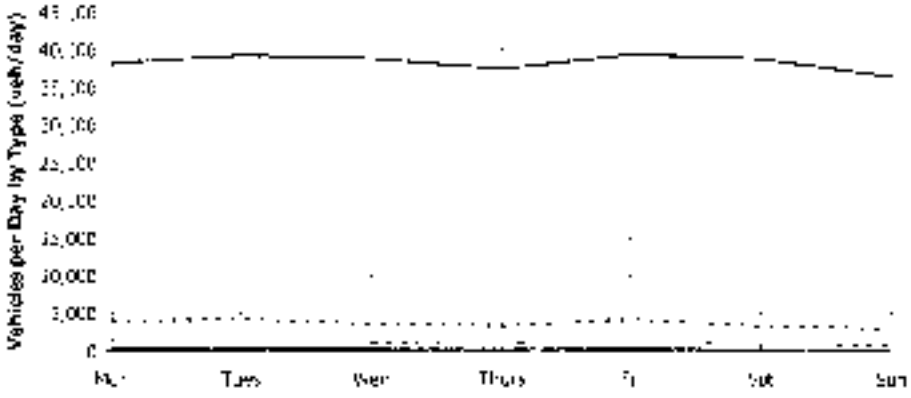

Exhibit 3-4
Daily Variation in Traffic by Vehicle Type for the Right Lane of an Urban Freeway

Daily volume variations by vehicle type through the week show higher weekday volumes and lower weekend volumes for truck traffic, with much smaller drops on the weekend for heavy truck traffic than for single-unit trucks. Car and pickup traffic peaks on Fridays and declines much more subtly on weekends on this urban freeway.

Note: Northbound Highway 26 north of I-5, Tacoma, Washington.

Hourly Variations

Typical hourly variation patterns for rural routes are shown in Exhibit 3-5, where the patterns are related to highway type and day of the week. Unlike urban routes, rural routes tend to have a single peak that occurs in the afternoon. A small morning peak is visible on weekdays that is much lower than the afternoon peak. The proportion of daily traffic occurring in the peak hour is much higher for recreational access routes than for intercity or local rural routes.

AR0073845

The weekend pattern for recreational routes is similar to the weekday pattern, as travelers tend to go to their recreation destination in the morning and return in the later afternoon. Weekend morning travel is considerably lower than weekday morning travel for most other types of rural routes.

The repeatability of hourly variations is of great importance. The stability of peak-hour demand affects the feasibility of using such values in design and operational analyses of highways and other transportation facilities. Exhibit 3-6 shows data obtained for single directions of urban streets in metropolitan Toronto. The data were obtained from detectors measuring traffic in one direction only, as evidenced by the single peak period shown for either morning or afternoon. The area between the dotted lines indicates the range within which one can expect 95% of the observations to fall. Whereas the variations by hour of the day are typical for urban areas, the relatively narrow and parallel fluctuations among the days of the study indicate the repeatability of the basic pattern.

Exhibit 3-6
Repeatability of Hourly Traffic Variations for Urban Streets

Repeatability of hourly patterns

Peak Hour and Analysis Hour

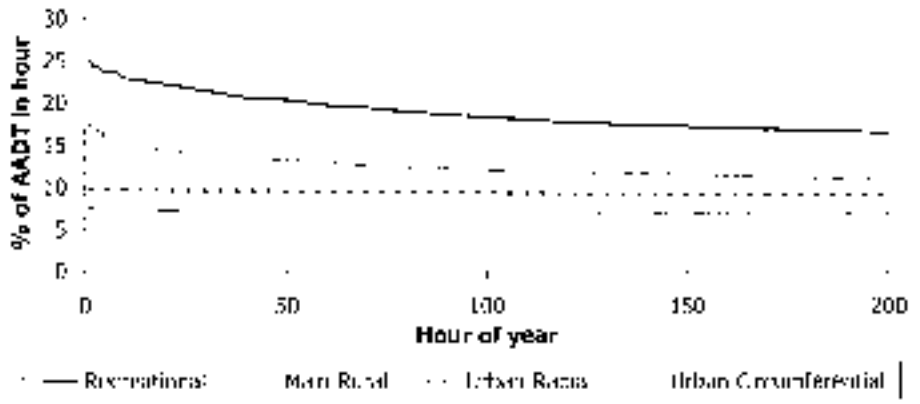
Capacity and urban traffic analysis usually focus on the peak-hour traffic volume because it represents the most critical period for operations and has the highest capacity requirements. However, as shown in the previous sections, the peak hour volume is not a constant value from day to day or from season to season.

If the highest hourly volumes for a given location were listed in descending order, the data would vary greatly, depending on the type of facility. Rural and recreational routes often show a wide variation in peak-hour volumes. Several extremely high volumes occur on a few select weekends or in other peak periods, and traffic during the rest of the year flows at much lower volumes, even during the peak hour. Urban streets, on the other hand, show less variation in peak-hour traffic. Most users are daily commuters or frequent users, and occasional and special event traffic is minimal. Furthermore, many urban routes are filled to capacity during each peak hour, and variation is therefore severely constrained—an issue that will be revisited later in this section.

AR0073847

Exhibit 3-7 shows hourly volume relationships measured on four highway types in Washington. The recreational highway shows the widest variation in peak hour traffic. Its values range from 25% of AADT in the busiest hour of the year to about 10.5% in the 200th busiest hour of the year. The main rural freeway also varies widely, with 17.0% of the AADT in the highest hour, decreasing to 10.5% in the 200th-highest hour. The urban freeways show far less variation. The range in percent of AADT covers a narrow band, from approximately 9.7% (radial freeway) and 7.3% (circumferential freeway) for the highest hour to 8.9% and 6.9%, respectively, for the 200th-highest hour. Exhibit 3-7 is based on all hours of the year, not just peak hours of each day, and shows only the highest 200 hours of the year.

Exhibit 3-7
Ranked Hourly Volumes



Notes: Recreational, Two-Lane Mixed Pass (AADT = 7,000); Main Rural, Four-Lane Mixed Pass (AADT = 20,000); Urban Radial, Eight-Lane Freeway (AADT = 128,170); Urban Circumferential, Eight-Lane Freeway (AADT = 241,550).

Selection of an analysis hour usually implies that a small portion of the demand during a year will not be adequately served.

The selection of an appropriate hour for planning, design, and operational purposes is a compromise between providing an adequate LOS for every (or almost every) hour of the year and providing economic efficiency. Customary practice in the United States is to base rural highway design on the 30th-highest hour of the year. There are few hours with higher volumes than this hour, while there are many hours with volumes not much lower. In urban areas, there is usually little difference between the 30th- and 200th-highest hours of the year, because of the recurring morning and afternoon commute patterns (4).

The selection of the analysis hour should consider the impact on the design and operations of higher-volume hours that are not accommodated. The recreational access route curve of Exhibit 3-7 shows that the highest hours of the year have one-third more volume than the 100th-highest hour, whereas the highest hours of an urban radial route were only about 6% higher than the volume at the 100th-highest hour. Use of a design criterion set at the 100th-highest hour would create substantial congestion on a recreational access route during the highest-volume hours but would have less effect on an urban facility. Another consideration is the LOS objective. A route designed to operate at LOS C can absorb larger amounts of additional traffic than a route designed to operate at LOS D or E during the hours of the year operating with higher volumes than the design hour. As a general guide, the most frequently occurring peak volumes

AR0073848

may be considered in the design of new or upgraded facilities. The LOS during higher-volume periods should be tested to determine the acceptability of the resulting traffic conditions.

Narrower traffic volume patterns may not reflect actual demand patterns

On roadways where oversaturation occurs during peak periods, analysts should be particularly careful in selecting a design hour, since measured traffic volumes may not reflect the changes in demand that occur once a bottleneck is removed. Exhibit 3-8 shows hourly variations in traffic on an urban freeway before and after the freeway was widened. In the before condition, the freeway's observed volumes were constrained by a bottleneck between 6 and 10 a.m., as indicated by the flat volume line. After the freeway widening, a more typical a.m. peak occurred, since travel patterns more closely reflected when travelers desired to travel rather than when the freeway could accommodate their travel.

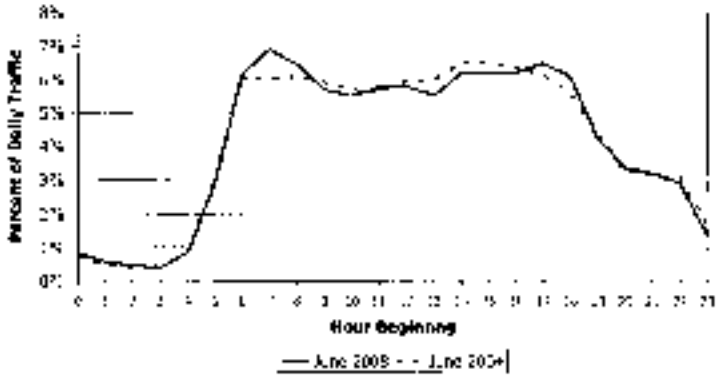

Exhibit 3-8
Example of a Change in Travel Patterns Following Removal of a Capacity Constraint

Note: I-25 south of US 6, Denver.
Source: Colorado DOT.

As used in the HCM, the *K*-factor is the proportion of AADT that occurs during the peak hour. For many rural and urban highways, this factor falls between 0.08 and 0.10. For highway sections with high peak periods and relatively low off-peak flows, the *K*-factor may exceed 0.10. Conversely, for highways that demonstrate consistent and heavy flows for many hours of the day, the *K*-factor is likely to be lower than 0.08. In general,

- The *K*-factor decreases as the AADT on a highway increases;
- The *K*-factor decreases as development density increases; and
- The highest *K*-factors occur on recreational facilities, followed by rural, suburban, and urban facilities, in descending order.

The *K*-factor should be determined, if possible, from local data for similar facilities with similar demand characteristics.

AR0073849

Exhibit 3-9 demonstrates how K-factors decrease as AADT increases, on the basis of average data from Washington State.

Exhibit 3-9
Example *K* Factors by AADT

AADT	Average K-Factor	Number of Sites Included in Average K-Factor: Urban	Recreational	Other Rural
0–2,500	0.153	0	6	7
2,500–5,000	0.136	1	6	8
5,000–10,000	0.118	2	2	14
10,000–20,000	0.116	1	2	15
20,000–50,000	0.107	11	5	10
50,000–100,000	0.091	14	3	4
100,000–200,000	0.082	11	3	3
>200,000	0.087	2	3	3

Note: *K*-factors are for the 30th-highest traffic volume hour of the year.
Source: Washington State DOT (3).

Spatial Distributions

Traffic volume varies in space as well as time. The two critical spatial characteristics used to analyze capacity are directional distribution and volume distribution by lane. Volume may also vary longitudinally along various segments of a facility, but this does not explicitly affect HCM analyses because each facility segment that serves a different traffic demand is analyzed separately.

D-Factor

Concept of D-factor or directional distribution

The *D*-factor is the proportion of traffic moving in the peak direction of travel on a given roadway during the peak hours. A radial route serving strong directional demands into a city in the morning and out at night may display a 2:1 imbalance in directional flows. Recreational and rural routes may also be subject to significant directional imbalances, which must be considered in analyses. Circumferential routes and routes connecting two major cities within a metropolitan area may have very balanced flows during peak hours. Exhibit 3-10 provides examples of directional distributions from selected California freeways.

Exhibit 3-10
Example Directional Distribution Characteristics

Freeway Type	*D*-Factor
Rural–intercity	0.56
Rural–recreational and intercity	0.54
Suburban circumferential	0.52
Suburban radial	0.60
Urban radial	0.70
Intraurban	0.51

Notes: Rural–intercity, I-5 at Willows; rural–recreational and intercity, I-80 west of Donner Summit; suburban circumferential, I-680 in Danville; suburban radial, I-80 in Emeryville; urban radial, Highway 94 at I-5, San Diego; intraurban, I-880 in Hayward.
Source: Cothron, 2007.

Directional distribution is an important factor in highway capacity analysis. This is particularly true for two-lane rural highways. Capacity and level of service vary substantially with directional distribution because of the interactive nature of directional flows on such facilities—the flow in one direction of travel influences flow in the other direction by affecting the number of passing opportunities. Procedures for two-lane highway analyses include explicit consideration of directional distribution.

AR0073850

While the consideration of directional distribution is not mandated in the analysis of multilane facilities, the distribution has a dramatic effect on both design and LOS. As indicated in Exhibit 3-10, up to two-thirds of the peak-hour traffic on urban radial routes has been observed as moving in one direction. Unfortunately, the peak occurs in one direction in the morning and in the opposite direction in the evening. Thus, both directions of the facility must have adequate capacity for the peak directional flow. This characteristic has led to the use of reversible lanes on some urban streets and highways.

Directional distribution is not a static characteristic. It changes annually, hourly, daily, and seasonally. Development in the vicinity of highway facilities often changes the directional distribution.

The D-factor is used with the K-factor to estimate the peak-hour traffic volume in the peak direction, as shown by Equation 3-1.

$$DDHV = AADT \times K \times D$$

Equation 3-1

where

$DDHV$ = directional design hour volume (veh/h),

$AADT$ = annual average daily traffic (veh/day),

K = proportion of $AADT$ occurring in the peak hour (decimal), and

D = proportion of peak hour traffic in the peak direction (decimal).

Lane Distribution

Concept of lane distribution.

When two or more lanes are available for traffic in a single direction, the lane use distribution varies widely. The volume distribution by lane depends on traffic regulations, traffic composition, speed and volume, the number and location of access points, the origin–destination patterns of drivers, the development environment, and local driver habits.

Because of these factors, there are no typical lane distributions. Data indicate that the peak lane on a six-lane freeway, for example, may be the shoulder, middle, or median lane, depending on local conditions.

Exhibit 3-11 gives daily lane distribution data for various vehicle types on three selected freeways. These data are illustrative and are not intended to represent typical values.

Exhibit 3-11
Lane Distribution by Vehicle Type

Highway	Vehicle Type	Percent Distribution by Lane[a]		
		Lane 3	Lane 2	Lane 1
Lodge Freeway, Detroit	Light[b]	32.4	38.4	29.2
	Single unit trucks	7.7	61.5	40.8
	Combinations	6.6	2.9	38.5
	All vehicles	31.3	37.8	30.9
I-95, Connecticut Turnpike	Light[b]	24.5	40.9	34.6
	All vehicles	22.5	40.4	37.1
I-4, Orange, Florida	All vehicles	36.4	33.7	29.9

Notes: [a] Lane 1 = shoulder lane; lanes numbered from right to left.
[b] Passenger cars, panel trucks, and pickup trucks.
Source: Hulbert and Tracy (5), Florida DOT, 1993.

AR0073851

The trend indicated in Exhibit 3-11 is reasonably consistent throughout North America. However, vehicles tend to use the right-hand lanes, partially because they operate at lower speeds than other vehicles and partially because regulations may prohibit them from using the leftmost lanes.

Lane distribution must also be considered at intersections, since it affects how efficiently the demand for a particular movement can be served, as well as lane-by-lane queue lengths. Uneven lane distributions can be a result of upstream or downstream changes in the number of lanes available and the pre-positioning of traffic for downstream turning movements.

TRAVEL TIME VARIABILITY

Travelers using the same set of roadways notice that the time required to make their trip may vary from one day to the next. Depending on the importance of reaching one's destination by a given time (e.g., to start work, to pick up a child at day care, to deliver a shipment), one may budget extra time for the trip to allow for the possibility of a longer-than-usual travel time. This variability in travel times has several sources (7).

- *Traffic incidents* such as crashes, stalled cars, and debris in the roadway block travel lanes, reducing the roadway's capacity. Even when lanes are not physically blocked, activity on the shoulder (e.g., police activity) or in the opposite direction of travel (e.g., a crash scene being cleared) can lead to changes in driver behavior that result in congestion.
- *Work zones* may provide a reduced number of lanes or reduced clearances between vehicles (e.g., due to narrower lanes) and roadside objects (e.g., due to reduced or eliminated shoulders), which affect capacity. Speed limits may also be reduced in work zones. Temporary road closures may result in a diversion of traffic to other roadways, increasing traffic volumes on those roads above typical levels.
- *Environmental conditions* such as adverse weather, bright sunlight directly in drivers' eyes, and abrupt transitions from light to dark (such as at a tunnel entrance on a sunny day) may cause drivers to slow down and increase their spacing, resulting in a drop in a roadway's capacity.
- *Fluctuations in demand* occur both in longer-term patterns (by day of the week and by month of the year, as shown in Exhibit 3-1 through Exhibit 3-3) and more randomly from day to day, as shown in Exhibit 3-4. Variable traffic demand on a roadway with fixed capacity results in variable travel times.
- *Special events* are a special case of demand fluctuation occurring at known times relatively infrequently, resulting in traffic flow patterns that vary substantially from the typical situation.
- *Traffic control devices* that intermittently disrupt traffic flow (e.g., railroad crossings and drawbridges), as well as poorly timed traffic signals, contribute to travel time variability.
- *Inadequate base capacity*, interacting with the other six factors listed above, also influences travel time variability. Depending on how close a facility

AR0073852

is to operating at its capacity, relatively small changes in demand can result in disproportionately large changes in travel time. Facilities with a greater base capacity are less vulnerable to disruptions: a freeway with three lanes per direction that experiences an incident blocking one lane loses at least one-third of its directional capacity, while a freeway with two lanes per direction would lose at least one-half of its directional capacity.

AUTOMOBILE FACILITY TYPES

Exhibit 3-12 illustrates the kinds of automobile facilities addressed in the HCM. They are divided into two main categories: *uninterrupted-flow facilities*, where traffic has no fixed causes of delay or interruption beyond the traffic stream, and *interrupted-flow facilities*, where traffic control such as traffic signals and STOP signs introduce delay into the traffic stream.

(a) Freeway (b) Multilane Highway

(c) Two-Lane Highway (d) Urban Street

Exhibit 3-12
Automobile Facility Types

Uninterrupted Flow

Freeways are fully access-controlled, divided highways with a minimum of two lanes (and frequently more) in each direction. Certain lanes on freeways may be reserved for designated types of vehicles, such as high-occupancy vehicles or trucks. Some freeway facilities charge tolls, and their toll-collection facilities can create interrupted-flow conditions, such as on facilities where tolls are paid manually at toll plazas located on the freeway mainline. *Ramps* provide access to, from, and between freeways; some ramps have meters that control the flow of traffic onto a freeway segment.

AR0073853

Multilane highways are divided highways with a minimum of two lanes in each direction. They have zero or partial control of access. Traffic signals or roundabouts may create periodic interruptions to flow along an otherwise uninterrupted facility, but such interruptions are spaced at least 2 mi apart.

As the name implies, *two-lane highways* generally have a two-lane cross section, although passing and climbing lanes may be provided periodically. Within the two-lane sections, passing maneuvers must be made in the opposing lane. Traffic signals, STOP-controlled intersections, or roundabouts may occasionally interrupt flow, but at intervals longer than 2 mi.

Interrupted Flow

Urban streets are streets with relatively high densities of driveway and cross-street access, located within urban areas. The traffic flow of urban streets is interrupted (i.e., traffic signals, all-way stops, or roundabouts) at intervals of 2 mi or less. HCM procedures are applicable to arterial and collector urban streets, including those in downtown areas, but these procedures are not designed to address local streets.

MEASURED AND OBSERVED VOLUMES AND FLOW RATES

The direct observation of capacity is difficult to achieve for several reasons. The recording of a high, or even a maximum, volume or flow rate for a given facility does not ensure that a higher flow could not be accommodated at another time. Furthermore, capacity is sometimes an unstable operating condition. Depending on environmental factors, the mix of familiar and unfamiliar drivers in the traffic stream, and other considerations, the capacity achieved at a given location—or sets of otherwise similar locations—may vary from day to day.

HCM methodologies are based on calibrated national-average traffic characteristics observed over a range of facilities. Observations of these characteristics at specific locations will vary somewhat from national averages because of unique features of the local driving environment.

Freeways

HCM freeway capacity analysis procedures use a flow rate of 2,400 passenger cars per hour per lane (pc/h/ln) for basic freeway segments with free-flow speeds of 70 to 75 mi/h and 2,300 pc/h/ln for basic freeway segments with free-flow speeds of 65 mi/h as the capacity under base conditions.

Multilane Highways

The observation of multilane rural highways operating under capacity conditions is difficult, because such operations rarely occur. The HCM uses a flow rate of 2,200 pc/h/ln for multilane highways with free-flow speeds of 60 mi/h and 2,100 pc/h/ln for multilane highways with free-flow speeds of 55 mi/h as the capacity under base conditions.

Rural Two-Way, Two-Lane Highways

Two-way, two-lane rural highways in the United States and Canada rarely operate at volumes near capacity, and thus the observation of capacity

AR0073854

operations for such highways in the field is difficult. The HCM methodology reports *single-direction* capacities, with a flow rate of 1,700 pc/h/ln used as the capacity under base conditions.

Urban Streets

Since flow on urban streets is uninterrupted only on segments between intersections, the interpretation of high-volume observations on urban streets is not as straightforward as for uninterrupted-flow facilities. Signal timing significantly alters the capacity of such facilities by limiting the time that is available for movement along the urban street at critical intersections. The prevailing conditions on urban streets may vary greatly, and such factors as curb parking, transit buses, lane widths, and upstream intersections may substantially affect operations and observed volumes.

INTERACTIONS WITH OTHER MODES

Each mode that uses a roadway interacts with the other modal users of that roadway. This section examines the effects of other modes on the automobile mode; the effects of the automobile mode on other modes are discussed later in the portions of the chapter addressing those modes.

Pedestrians

Pedestrians interact with the automobile mode on interrupted-flow elements of the roadway system. At signalized intersections, the minimum green time provided for an intersection approach is influenced by the need to provide adequate time for pedestrians using the parallel crosswalk to cross the roadway safely. In turn, the green time allocated to a particular vehicular movement affects the capacity of and the delay experienced by that movement. At signalized and unsignalized intersections, turning vehicles must yield to pedestrians in crosswalks, which reduces the capacity of and increases the delay to those turning movements, compared with a situation in which pedestrians are not present. The increased delays at intersections and midblock pedestrian crossings along urban streets that result from higher pedestrian crossing volumes lower vehicular speeds along the urban street.

Bicycles

At intersections, automobile capacity and delay are affected by bicycle volumes, particularly where turning vehicles conflict with through bicycle movements. However, HCM methodologies only account for these effects at signalized intersections. Bicycles may also delay automobiles on two-lane roadways, in cases where bicycles use the travel lane, causing vehicles to wait for a safe opportunity to pass. This kind of delay is not currently accounted for in the HCM two-lane roadway methodology, which only addresses delays associated with waiting to pass other automobiles.

Transit

Transit vehicles are longer than automobiles and have different performance characteristics; thus, they are treated as heavy vehicles for all types of roadway

AR0073855

elements. At intersections, buses or streetcars that stop in the vehicular travel lane to serve passengers delay other vehicles in the lane and reduce the lane's capacity; however, this effect is only incorporated into the signalized intersection methodology. Special transit phases or bus signal priority measures at signalized intersections affect the allocation of green time to the various traffic movements, with accompanying effects on vehicular capacity and delay.

AR0073856

3. PEDESTRIAN MODE

OVERVIEW

Approximately 9% of all trips in the United States are accomplished by walking (2001 National Household Travel Survey). Moreover, many automobile trips and most transit trips include at least one section of the trip where the traveler is a pedestrian. Given the presence of a network of safe and convenient pedestrian facilities, as well as the availability of potential destinations within walking distance of one's trip origin, walking can be the mode of choice for a variety of shorter trips, including going to school, running errands, and recreational and exercise trips.

HUMAN FACTORS

A pedestrian is considerably more exposed than is a motorist, in both good and bad ways. A pedestrian travels much more slowly than other modal users and can therefore pay more attention to his or her surroundings. The ability to take in one's surroundings and get exercise while doing so can be part of the enjoyment of the trip. At the same time, a pedestrian interacts closely with other modal users, including other pedestrians, with potential safety, comfort, travel hindrance, and other implications. In addition, a pedestrian is exposed to the elements. As a result, a number of environmental and perceived safety factors significantly influence pedestrian quality of service. In locations with large numbers of pedestrians, pedestrian flow quality is also a consideration.

Some pedestrian flow measures are similar to those used for vehicular flow, such as the freedom to choose desired speeds and to bypass others. Others are related specifically to pedestrian flow, such as (a) the ability to cross a pedestrian traffic stream, to walk in the reverse direction of a major pedestrian flow, and to maneuver without conflicts or changes in walking speed and (b) the delay experienced by pedestrians at signalized and unsignalized intersections.

Environmental factors also contribute to the walking experience and, therefore, to the quality of service perceived by pedestrians. These factors include the comfort, convenience, safety, security, and economics of the walkway system. Comfort factors include weather protection, proximity, volume, and speed of motor vehicle traffic, pathway surface and pedestrian amenities. Convenience factors include walking distances, intersection delays, pathway directness, grades, sidewalk curbs, wayfinding signage and maps, and many features making pedestrian travel easy and uncomplicated.

Safety is provided by separating pedestrians from vehicular traffic both horizontally, by using pedestrian zones and other vehicle free areas, and vertically, by using overpasses and underpasses. Traffic control devices such as pedestrian signals can provide time separation of pedestrian and vehicular traffic, which improves pedestrian safety. Security features include lighting, open lines of sight, and the degree and type of street activity.

AR0073857

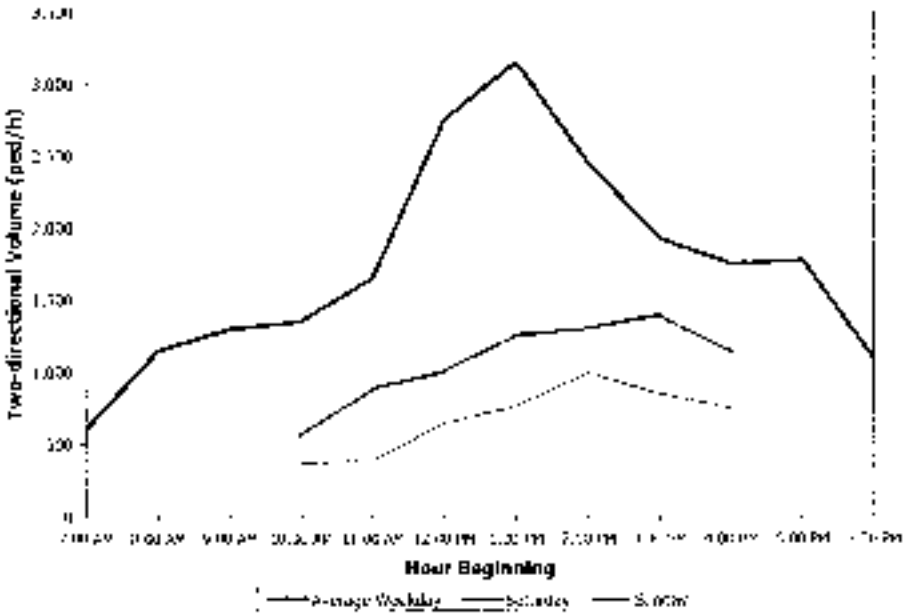
The economics of pedestrian facilities relate to user costs brought about by travel delays and inconvenience and to commercial values and retail development influenced by pedestrian accessibility.

Chapter 4, Traffic Flow and Capacity Concepts, discusses pedestrian flow measures, such as speed, space, and delay, while Chapter 5, Quality and Level-of-Service Concepts, covers the environmental factors that influence pedestrian quality of service.

VARIATIONS IN DEMAND

Pedestrian demand differs from the other modes addressed in the HCM in that the peak pedestrian demand often occurs at midday or during the early afternoon. Depending on the location, secondary peaks or plateaus in demand may also occur during the weekday a.m. and p.m. peak hours. Exhibit 3-13 shows two directional pedestrian volume data collected in May 2010 on a sidewalk in Lower Manhattan, for an average of five weekdays in a week, Saturday, and Sunday. Although weekday demand was considerably higher than weekend demand, a single peak can be seen clearly in all three counts. Work-related trips made up the majority of the peak period pedestrian trips, while non-work-related and tourist trips made up the majority of the midday and early afternoon pedestrian trips (8).

Exhibit 3-13
Temporal Variation in Pedestrian Demand

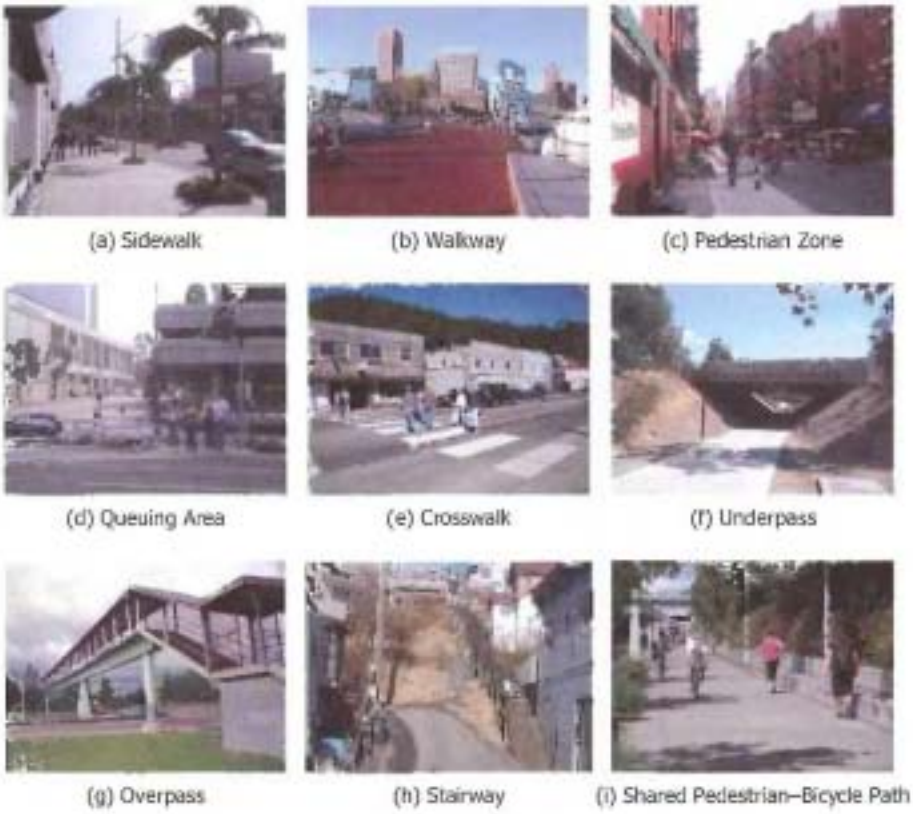


Source: Adapted from New York City Department of City Planning (8).

PEDESTRIAN FACILITY TYPES

Exhibit 3-14 illustrates the types of pedestrian facilities addressed in the HCM. The following sections define each type of facility.

AR0073858



(a) Sidewalk (b) Walkway (c) Pedestrian Zone

(d) Queuing Area (e) Crosswalk (f) Underpass

(g) Overpass (h) Stairway (i) Shared Pedestrian–Bicycle Path

Exhibit 3-14
Pedestrian Facility Types

Sidewalks, Walkways, and Pedestrian Zones

These three facility types are separated from motor vehicle traffic and typically are not designed for bicycles or other nonpedestrian users, other than persons in wheelchairs. They accommodate the highest volumes of pedestrians and provide the best levels of service, because pedestrians do not share the facility with other modes traveling at higher speeds.

Sidewalks are located parallel and in proximity to roadways. Pedestrian walkways are similar to sidewalks in construction and may be used to connect sidewalks, but they are located well away from the influence of automobile traffic. Pedestrian zones are streets that are dedicated to pedestrian use on a full- or part-time basis.

Pedestrian walkways are also used to connect portions of transit stations and terminals. Pedestrian expectations about speed and density in a transit context are different from those in a sidewalk context; the *Transit Capacity and Quality of Service Manual* (TCQSM) (9) provides more information on this topic.

Queuing Areas

Queuing areas are places where pedestrians stand temporarily while waiting to be served, such as at the corner of a signalized intersection. In dense standing crowds, there is little room to move, and circulation opportunities are limited as the average space per pedestrian decreases.

AR0073859

Pedestrian Crosswalks

Pedestrian crosswalks, whether marked or unmarked, provide connections between pedestrian facilities across sections of roadway used by automobiles, bicycles, and transit vehicles. Depending on the type of control used for the crosswalk, local laws, and driver observance of those laws, pedestrians will experience varying levels of delay, safety, and comfort while waiting to use the crosswalk.

Stairways

Stairways are sometimes used to help provide pedestrian connectivity in areas with steep hills, employing the public right-of-way that would otherwise contain a roadway. Today they are often also used in conjunction with a ramp or elevator to provide shorter access routes to overpasses, underpasses, or walkways located at a different elevation. Even a small number of pedestrians moving in the opposite direction of the primary flow can significantly decrease a stairway's capacity to serve the primary flow.

Overpasses and Underpasses

Overpasses and underpasses provide a grade-separated route for pedestrians to cross wide or high-speed roadways, railroad tracks, busways, and topographic features. Access is typically provided by a ramp or, occasionally, an elevator, which is often supplemented with stairs. Procedures exist to assess the quality of pedestrian flow on these facilities, but not the quality of the pedestrian environment.

Shared Pedestrian–Bicycle Paths

Shared pedestrian paths typically are open to use by nonmotorized modes such as bicycles, skateboards, and inline skaters. Shared-use paths often are constructed to serve areas without city streets and to provide recreational opportunities for the public. These paths are common on university campuses, where motor vehicle traffic and parking are often restricted. In the United States, there are few paths exclusively for pedestrians; most off-street paths, therefore, are for shared use.

On shared facilities, bicycles—because of their markedly higher speeds—can have a negative effect on pedestrian capacity and quality of service. However, it is difficult to establish a bicycle–pedestrian equivalent because the relationship between the two depends on the characteristics of the cycling population and the modes' respective flows, directional splits, and other factors.

INTERACTIONS WITH OTHER MODES

Automobiles

At signalized intersections, the delay experienced by pedestrians is influenced in part by the amount of green time allocated to serve vehicular volumes on the street being crossed. The volume of cars making turns across a crosswalk at an intersection also affects a pedestrian's delay and perception of the intersection's quality of service.

AR0073860

At unsignalized intersections, increased major-street traffic volumes affect pedestrian crossing delay by reducing the number of opportunities for pedestrians to cross. The effect of motor vehicle volumes on pedestrian delay at unsignalized intersections also depends on local laws specifying yielding requirements to pedestrians in crosswalks and driver observation of those laws.

Automobile and heavy vehicle traffic volumes, and the extent to which pedestrians are separated from vehicular traffic, influence pedestrians' perceptions or quality of service while using a sidewalk.

Bicycles

Bicycle interaction with pedestrians is greatest on pathways shared by the two modes. Bicycles—because of their markedly higher speeds—can have a negative effect on pedestrian capacity and quality of service on such pathways.

Transit

The interaction of transit vehicles with pedestrians is similar to that of automobiles. However, because transit vehicles are larger than automobiles, the effect of a single transit vehicle is proportionately greater than that of a single automobile. The lack of pedestrian facilities in the vicinity of transit stops can be a barrier to transit access, and transit quality of service is influenced by the quality of the pedestrian environment along streets with transit service. Although it is not addressed by the HCM procedures, the pedestrian environment along the streets used to get to and from the streets with transit service also influences transit quality of service. Passengers waiting for buses at a bus stop can reduce the effective width of a sidewalk, while passengers getting off buses may create cross-flows that interact with the flow of pedestrians along a sidewalk.

AR0073861

4. BICYCLE MODE

OVERVIEW

Bicycles are used to make a variety of trips, including trips for recreation and exercise, commutes to work and school, and trips for errands and visiting friends. Bicycles help extend the market area of transit service, since bicyclists can travel about five times as far as an average person can walk in the same amount of time. Although bicycle trip-making in North America is lower than in the rest of the world, several large North American cities that have invested in bicycle infrastructure and programs (e.g., Portland, Oregon; Minneapolis, Minnesota; and Vancouver, Canada) have bicycle commute mode splits around 4 % (2005–2007 census and local data). Some college towns like Eugene, Oregon, and Boulder, Colorado, have commute mode splits exceeding 8% (2007 census data), and Davis, California, achieved a 14% mode split (2005–2007 census data).

HUMAN FACTORS

Many of the measures of vehicular effectiveness can also describe bicycling conditions, whether on exclusive or shared facilities. As with motor vehicles, bicycle speeds remain relatively insensitive to flow rates over a wide range of flows. Delays due to traffic control affect bicycle speeds along a facility, and the additional effort required to accelerate from a stop is particularly noticeable to bicyclists. Grades, bicycle gearing, and the bicyclist's fitness level also affect bicycle speed and the level of effort required to maintain a particular speed.

Some vehicular measures are less applicable to the bicycle mode. For example, bicycle density is difficult to assess, particularly with regard to facilities shared with pedestrians and others. Because of the severe deterioration of service quality at flow levels well below capacity (e.g., freedom to maneuver around other bicyclists), the concept of capacity has little utility in the design and analysis of bicycle paths and other facilities. Capacity is rarely observed on bicycle facilities; rather, cyclists typically dismount and walk their bicycles before a facility reaches capacity. Values for capacity therefore reflect sparse data, generally from European studies or traffic simulation.

Bicycle as a pedestrian enabler.

Other measures of bicycle quality of service have no vehicular counterpart. For example, the concept of bicycle delay relates directly to bicyclists' comfort and convenience (*10*). During travel on a bicycle facility, two significant parameters can be easily observed and identified: (*a*) the number of users (other bicyclists, pedestrians, etc.) moving in the same direction and passed by the bicyclist and (*b*) the number of users moving in the opposing direction encountered by the bicyclist. Each event causes some discomfort and inconvenience to the bicyclist.

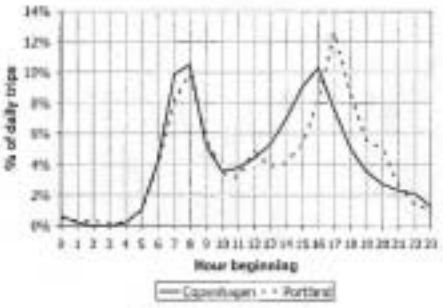
As is the case with pedestrians, environmental factors contribute significantly to the bicycling experience and, therefore, to quality of service. These factors include the volume and speed of adjacent vehicles, heavy vehicle presence, the presence of on-street parking, and the quality of the pavement. Chapter 5, Quality and Level-of-Service Concepts, discusses environmental and disturbance factors, while Chapter 4, Traffic Flow and Capacity Concepts, presents bicycle flow measures.

AR0073862

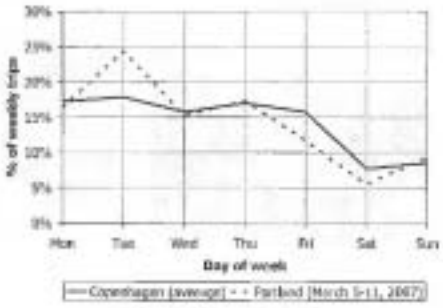
VARIATIONS IN DEMAND

Bicycle travel demand varies by time of day, day of the week, and month of the year. All of these variations in demand are related to trip-making demands in general (e.g., bicycle demand is highest during weekday a.m. and p.m. peak periods, just as with motor vehicles). Bicyclists are more exposed than motorists to the elements and other roadway users. Dutch research has shown that weather explains up to 80% of annual variation in bicycle travel, with higher rainfall and lower temperatures resulting in lower rates of bicycling (*11*).

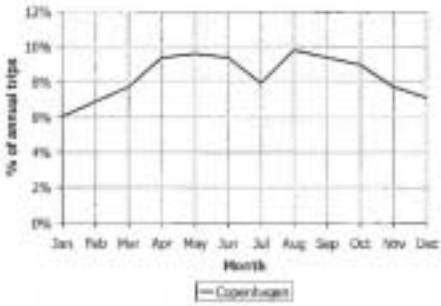
Therefore, monthly variations in bicycle demands are also weather- and daylight-related. Exhibit 3-15 shows variations in bicycle demand hourly, daily, and monthly, on the basis of data from Copenhagen, Denmark, and Portland, Oregon. Exhibit 3-16 shows observations of bicycle demand compared with variations in daily high temperature along a bicycle path in Boulder, Colorado.



(a) Hourly Variations



(b) Weekly Variations



(c) Monthly Variations

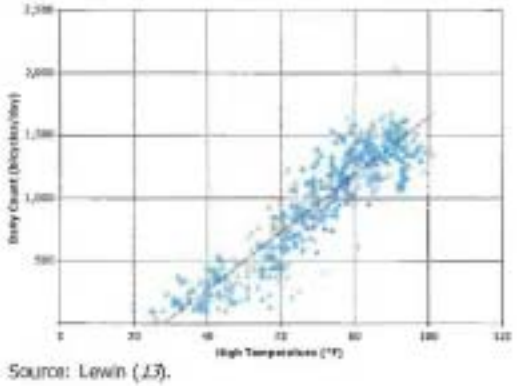
Source: Municipality of Copenhagen (*12*); Portland Office of Transportation, 2007.

Exhibit 3-15
Temporal Variations in Bicycle Demand

Copenhagen and Portland hourly demand patterns are nearly identical through noon. In the afternoon, Copenhagen peaks an hour earlier (due to a shorter workday length). The Portland p.m. peak is noticeably higher than the a.m. peak, unlike Copenhagen.

Bicycle volumes can fluctuate significantly from day to day, as suggested by the Portland line on the weekly variation chart. The Portland volumes may reflect the effects of rain on Wednesday, Friday, Saturday, and Sunday of that week.

Automobile volumes also drop in July in Copenhagen, when many people go on vacation. Except for July, months with higher temperatures and more daylight have higher bicycle volumes in Copenhagen.



Source: Lewin (*13*).

Exhibit 3-16
Example Variations in Bicycle Demand due to Temperature

AR0073863

BICYCLE FACILITY TYPES

Exhibit 3-17 illustrates the types of bicycle facilities addressed in the HCM. The facilities are divided into two types, on-street and off-street, and include situations where a facility is shared with users of another mode (e.g., a lane shared by bicyclists and motor vehicle traffic or a pathway shared by bicyclists and pedestrians).

Exhibit 3-17
Bicycle Facility Types

(a) Shared Lane (b) Bicycle Lane (c) Shoulder Bikeway

(d) Sidepath (e) Bicycle Track (f) Exclusive Pathway

On-Street Bicycle Facilities

On-street bicycle facilities include roadways on which bicycles share a travel lane with motorized vehicular traffic, dedicated on-street bicycle lanes, paved roadway shoulders available for use by bicyclists, and bicycle tracks—mainly seen in Europe—located between the roadway and the sidewalk and separated from each by low curbs. For each facility type, bicycle flow is one-way. The quality of bicycle flow, safety, and the bicycling environment are all considerations for these types of facilities.

Off-Street Bicycle Facilities

Off-street bicycle facilities consist of pathways dedicated to the exclusive use of bicyclists and pathways shared with pedestrians and other types of users. These types of facilities may be located parallel and in proximity to roadways (*sidepaths*), or they may be completely independent facilities, such as recreational trails along former railroad rights-of-way and off-street pathways of the kind found in city parks and on college campuses. Bicycle flow along these types of facilities is typically two-way and is often shared with users of other modes. The number of meeting and passing events between cyclists and other path users affects the quality of service for bicyclists using these facility types. The presence and design of driveways and intersections may affect the quality of service of bicyclists on side paths but is not addressed by HCM procedures.

AR0073864

MEASURED AND OBSERVED VOLUMES

Exhibit 3-18 provides daily two-directional bicycle volumes on selected U.S. roadways and bicycle facilities. Data were collected on weekdays, generally in late spring or summer, so these volumes represent peak conditions for the year. In comparison, the highest-volume roadways in Copenhagen, Denmark, have two-directional daily bicycle volumes exceeding 30,000 on spring and fall weekdays with good weather (12).

Exhibit 3-18
Daily Weekday Bicycle Volumes on Selected U.S. Bicycle Facilities (2006–2008)

Facility	Location	Facility Type	Daily Bicycle Volume
Hawthorne Bridge	Portland, OR	Shared pedestrian–bicycle path	7,400
Russell Boulevard	Davis, CA	Shared pedestrian–bicycle path	6,700
Broadway Bridge	Portland, OR	Shared pedestrian–bicycle path	4,300
North Vancouver Street	Portland, OR	Bicycle lane	3,500
Hudson River Greenway	New York, NY	Shared pedestrian–bicycle path	3,500
Steel Bridge	Portland, OR	Shared pedestrian–bicycle path	3,000
Waterfront Park	Portland, OR	Shared pedestrian–bicycle path	3,000
Williamsburg Bridge	New York, NY	Shared pedestrian–bicycle path	3,000
Springwater Trail	Portland, OR	Shared pedestrian–bicycle path	2,800

INTERACTIONS WITH OTHER MODES

Automobiles

Vehicular and heavy vehicle traffic volumes and speeds, the presence of on-street parking (which presents the potential for bicyclists to hit or be hit by car doors), and the degree to which bicyclists are separated from automobile traffic all influence bicyclists' perceptions of the quality of service received while using an on-street bicycle facility. Turning vehicles, particularly right-turning vehicles that cross the path of bicyclists, also affect quality of service.

Pedestrians

The effect of pedestrians on bicycles is greatest on pathways shared by the two modes. Pedestrians—because of their markedly lower speeds and tendency to travel in groups several abreast—can have a negative effect on bicycle quality of service on such pathways. Similar to pedestrian impacts on motor vehicles, bicyclists must yield to crossing pedestrians, and the signal timing at intersections reflects, in part, the time required for pedestrians to cross the street.

Transit

Transit vehicles interact with bicycles in much the same way as automobiles. However, because transit vehicles are heavy vehicles, the effect of a single transit vehicle is proportionately greater than that of a single automobile. Buses can also affect bicyclists when they pull over into a bicycle lane or paved shoulder to serve a bus stop; however, this impact is not accounted for in HCM procedures. Although not addressed by HCM procedures, the availability of good bicycle access extends the capture shed of a transit stop or station, and when bicycles can be transported by transit vehicles, transit service can greatly extend the range of a bicycle trip.

AR0073865

5. TRANSIT MODE

OVERVIEW

Transit plays two major roles in North America. First, it accommodates choice riders—those who choose transit for their mode of travel even though they have other means available. These riders choose transit to avoid congestion, save money on fuel and parking, use their travel time productively for other activities, and reduce the impact of automobile driving on the environment, among other reasons. Transit is essential for mobility in the central business districts (CBDs) of some major cities, which could not survive without it.

The other major role of transit is to provide basic mobility for segments of the population that are unable to drive for age, physical, mental, or financial reasons. About 11% of the adult population in the United States does not have a driver's license (*14*) and must depend on others to transport them in automobiles, on transit, or via other modes, including walking, bicycling, and taxis. These transit users have been termed captive riders.

Exhibit 3-19 provides examples of peak-hour trips by transit to the downtowns of selected U.S. cities. The variations in transit use reflect differences in population, CBD employment, extent of bus and rail transit services, and geographic characteristics.

Exhibit 3-19
Transit Commuting to Downtowns (2000)

Area	Transit Share of Downtown Commuters	Area	Transit Share of Downtown Commuters
New York	76.5%	Los Angeles	20.3%
Chicago	61.7%	Houston	16.7%
Boston	50.9%	Dallas	13.6%
San Francisco	49.0%	Sacramento	12.3%
Philadelphia	45.7%	San Diego	11.4%
Washington, DC	37.8%	San Antonio	7.2%
Seattle	36.8%	Austin	3.8%
Portland	27.5%		

Source: *Commuting in America III* (*15*), adapted from "Commuting to Downtown in America: Census 2000," report to the Transportation Research Board Subcommittee on Census Data for Transportation Planning, Jan. 10, 2005.

HUMAN FACTORS

Transit passengers frequently rely on other modes to gain access to transit. Transit use is greater where population densities are higher and pedestrian access is good. Typical transit users do not have transit service available at the door and must walk, bicycle, or drive to a transit stop and walk or bicycle from the transit discharge point to their destination. In contrast, suburban areas are mainly automobile-oriented, with employment and residences dispersed, often without sidewalks or direct access to transit lines. If potential passengers cannot access service at both ends of their trip, transit is not an option for that trip.

Unlike the other modes addressed in the HCM, transit is primarily focused on a service rather than a facility. Roadways, bicycle lanes, and sidewalks, once constructed, are generally available at all times to users. Transit service, in contrast, is only available at designated times and places. Another important difference is that transit users are passengers, rather than drivers, and not in

AR0073866

direct control of their travel. Thus, the frequency and reliability of service are important quality-of-service factors for transit users. Travel speed and comfort while making a trip are also important to transit users.

Transit is about moving people rather than vehicles. Transit operations at their most efficient level involve relatively few vehicles, each carrying a large number of passengers. In contrast, roadway capacity analysis typically involves relatively large numbers of vehicles, most carrying only a single occupant. In evaluating priority measures for transit and automobile users, the number of people affected is often more relevant than the number of vehicles.

ON-STREET TRANSIT CHARACTERISTICS

The TCQSM comprehensively addresses transit modes.

The HCM addresses only those major transit modes (in terms of passengers carried) that operate on streets and interact with other users of streets and highways. These modes are buses, streetcars, and light rail, illustrated in Exhibit 3-20 and described briefly in the following sections.

(a) Bus (b) Streetcar (c) Light Rail

Exhibit 3-20
Transit Modes Addressed in the HCM

Bus

Demand-responsive transit (with flexible schedules or routes, or both) is not addressed by the HCM but is addressed in the TCQSM.

The bus mode is operated by rubber-tired vehicles that follow fixed routes and schedules along roadways. Although the electric trolleybus (a bus receiving its power from overhead wires) is classified as a separate mode by the Federal Transit Administration (FTA), for the purposes of the HCM, it is also considered a bus. In 2007, more than 53% of all transit passenger boardings in the United States occurred on buses (*16*).

The bus mode offers considerable operational flexibility. Service can range from local buses stopping every two to three blocks along a street, to limited-stop service stopping every ½ to 1 mi, to express service that travels along a roadway without stopping. Buses may stop in the travel lane (*on-line*) or in a parking lane or pullout (*off-line*). On-line stops reduce bus delay but may increase vehicle and bicycle delay. Because buses frequently carry more people than the vehicles stopped behind them, on-line stops may help reduce overall person delay.

Streetcar

The streetcar mode is operated by vehicles that receive power from overhead wires and run on tracks. For FTA reporting purposes, streetcars are considered to be a form of light rail. For HCM purposes, the following operating and physical characteristics distinguish streetcars from light rail:

- Generally shorter (typically one-car) trains, with slightly narrower cars;
- Greater potential for onboard fare payment, which may affect dwell times;

AR0073867

- Greater prevalence of mixed-traffic operation; and
- More frequent stops.

Streetcars make on-line stops, which minimizes their delay leaving a station, but may increase delay to vehicles and bicycles stopped behind the streetcar.

Light Rail

As is streetcar, light rail is a mode operated by vehicles that receive power from overhead wires and that run on tracks. Trains typically consist of multiple cars; fares are typically paid to a machine on the station platform (thus allowing passengers to board through all doors, reducing dwell time); station spacing tends to be relatively long, particularly outside downtown areas; and traffic signal preemption or priority is frequently employed.

The HCM only addresses light rail operations along roadways. Consult the TCQSM for a more comprehensive treatment of light rail.

When light rail operates along a roadway, it typically does so in an exclusive lane or in a segregated right-of-way in the street median or along the side of the street. Most light rail routes include lengthy sections where tracks are located in a separate, potentially grade-separated right-of-way and any interaction with traffic occurs at gate-controlled grade crossings.

TRAVEL TIME VARIABILITY

As do motorists, transit riders often allow extra time for time-sensitive trips. Sources of bus travel time variability include all of the factors listed in the automobile section of this chapter, plus bus-specific factors such as variations in passenger demands (day-to-day and bus-to-bus), traffic signal delays after stopping to serve passengers, wheelchair lift and bicycle rack usage, differences in bus operator experience, route length, and the number of stops (9).

ON-STREET TRANSIT FACILITY TYPES

Mixed Traffic

More than 99% of the bus route miles in the United States are operated in mixed traffic. In contrast, most rail route miles—other than portions of streetcar lines—operate in some form of segregated right-of-way. In mixed traffic, transit vehicles are subject to the same causes of delay as are automobiles, and they need to stop periodically to serve passengers. These stops can cause transit vehicles to fall out of any traffic signal progression that might be provided along the street, causing them to incur greater amounts of signal delay than other vehicles.

Exclusive Lanes

Exclusive lanes are on-street lanes dedicated for use by transit vehicles, on either a full-time or part-time basis. They are generally separated from other lanes by just a stripe, and buses may be able to leave the exclusive lane to pass buses or obstructions such as delivery trucks. Right-turning traffic, bicycles, carpools, and taxis are sometimes allowed in exclusive bus lanes. Generally, no other traffic, with the possible exception of transit buses, is allowed in exclusive lanes provided for rail transit vehicles. Exclusive lanes allow transit vehicles to bypass queues of vehicles in the general traffic lanes and reduce or eliminate

AR0073868

delays to transit vehicles caused by right-turning traffic. Therefore, these lanes can provide faster, more reliable transit operations.

On-Street Transitways

Buses and trams sometimes operate within a portion of the street right-of-way that is physically segregated from other traffic in the median or adjacent to one side of the street. No other traffic is allowed in the transitway. The amount of green time allocated to transit vehicles may be different from the amount of time allocated to the parallel through movements—for example, it might be reduced to provide time to serve conflicting vehicular turning movements.

MEASURED AND OBSERVED VOLUMES

Exhibit 3-21 provides examples of observed peak-direction, peak-hour bus and passenger flows along selected roadways in the United States and Canada. Higher bus volumes have been observed on busways in South America; they require a combination of passing lanes at stations for express services and multiple-platform stations at major transfer points and downtown terminals.

Exhibit 3-21
Observed On-Street, Peak-Direction, Peak Hour Bus and Passenger Volumes (1995–2000)

Location	Facility	Peak-Hour Peak-Direction Buses	Peak-Hour Peak-Direction Passengers
Ottawa	Albert St./Slater St.	100	10,000
New York City	Madison Ave.	160	10,000
Portland	5th Ave./6th Ave.	175	9,300
Newark	Broad St.	150	6,000
Denver	Broadway/Lincoln St.	90	2,300
Boston	Tours St./High St.	90	2,000
Vancouver	Granville Mall	70	1,300

Source: Hoorweg (17), TCRP Report 90, Volume 2 (18), TCQSM (4).

INTERACTIONS WITH OTHER MODES

Automobiles

Higher automobile volumes result in greater delays for all motorized traffic, including buses. In locations where buses pull out of the travel lane to serve bus stops and yield-to-bus laws are not in place (or generally observed), buses experience delay waiting for a gap to pull back into traffic after serving a stop. Day-to-day variations in roadway congestion and trip-to-trip variations in making or missing green phases at signalized intersections affect bus schedule reliability, although no HCM techniques exist to predict this impact.

Pedestrians

Transit users are typically pedestrians immediately before and after their trip aboard a transit vehicle, so the quality of the pedestrian environment along access routes to transit stops also affects the quality of the transit trip. Pedestrians can also delay buses in the same way that they delay automobiles, as described earlier in this chapter.

Bicycles

In locations where buses pull out of the travel lane to serve bus stops, bicycles may delay buses waiting for a gap to pull back into traffic, similar to

AR0073869

automobiles. Transit users may be bicyclists before or after their trip, so the quality of the bicycling environment along access routes to transit stops also influences the quality of the transit trip.

The relationships between volume (flow rate), speed, and density are among the most fundamental in transportation engineering. Chapter 4, **Traffic Flow and Capacity Concepts**, describes how these basic relationships apply to the four modes covered by the *Highway Capacity Manual* (HCM): automobiles, pedestrians, bicycles, and on-street transit. Details of these relationships specific to automobiles operating on a particular system element (for example, speed–flow curves for freeways) are provided in the appropriate methodological chapters of Volumes 2 and 3.

Capacity represents the maximum sustainable hourly flow rate at which persons or vehicles reasonably can be expected to traverse a point or a uniform section of a lane or roadway during a given time period under prevailing roadway, environmental, traffic, and control conditions. Reasonable expectancy is the basis for defining capacity. The stated capacity for a given system element is a flow rate that can be achieved repeatedly for peak periods of sufficient demand, as opposed to being the maximum flow rate that might ever be observed. System elements that have different prevailing conditions will have different capacities, and the maximum flow rate observed for a given system element may vary from day to day.

Several of the operational performance measures presented in Chapter 4 (speed, delay, and density, in particular) are used in Chapter 5 to describe the quality of service provided by a roadway, or—in the case of the volume to capacity (demand-to-capacity) ratio—are used to define the threshold between Levels of Service (LOS) E and F.

AR0073875

2. AUTOMOBILE MODE

A few basic variables—volume, flow rate, speed, and density—can be used to describe traffic flow on any roadway. In the HCM, volume, flow rate, and speed are parameters common to both uninterrupted- and interrupted-flow facilities, but density applies primarily to uninterrupted flow. Some parameters related to flow rate, such as spacing and headway, are also used for both types of facilities. Other parameters, such as saturation flow and gap, are specific to interrupted flow.

BASIC AUTOMOBILE FLOW PARAMETERS

Volume and Flow Rate

Volume and flow rate are two measures that quantify the number of vehicles passing a point on a lane or roadway during a given time interval. These terms are defined as follows:

- *Volume*—the total number of vehicles that pass over a given point or section of a lane or roadway during a given time interval; any time interval can be used, but volumes are typically expressed in terms of annual, daily, hourly, or subhourly periods.
- *Flow rate*—the equivalent hourly rate at which vehicles pass over a given point or section of a lane or roadway during a given time interval of less than 1 h, usually 15 min. This chapter focuses on flow rate and the variations in flow that can occur over the course of an hour.

Flow rate is the equivalent hourly volume that would occur if a subhourly time was observed for an entire hour.

There is a distinction between volume and flow rate. Volume is the number of vehicles observed or predicted to pass a point during a time interval. Flow rate represents the number of vehicles passing a point during a time interval less than 1 h, but expressed as an equivalent hourly rate. A flow rate is the number of vehicles observed in a subhourly period, divided by the time (in hours) of the observation. For example, a volume of 100 veh observed in a 15-min period implies a flow rate of 100 veh divided by 0.25 h, or 400 veh/h.

Observed volumes may reflect capacity constraints rather than true demand. Demand is usually the desired input to HCM analyses, although it is not always easy to determine.

Volume and flow rate are variables that help quantify *demand*, that is, the number of vehicle occupants or drivers (usually expressed as the number of vehicles) who desire to use a given system element during a specific time period, typically 1 h or 15 min. As discussed in Chapter 3, Modal Characteristics, observed volumes may reflect upstream capacity constraints rather than the true demand that would exist without the presence of a bottleneck.

In many cases, demand volumes are the desired input to HCM analyses. (An exception would be, for example, when one is interested in analyzing traffic conditions downstream of a bottleneck that is not planned to be removed.) When conditions are undersaturated and no upstream bottlenecks exist, demand volume at a location can be assumed to be equivalent to the measured volume at that location. Otherwise, ascertaining demand requires a count of undersaturated traffic upstream of a bottleneck (i.e., a count of arrival volume rather than departure volume) (1). When the queue from a bottleneck extends past the

AR0073876

previous intersection or interchange, it may not be easy to determine how much of the traffic approaching the end of the queue is actually destined for the bottleneck location. Furthermore, as illustrated in Chapter 3, demand patterns may change after a bottleneck is removed. Nevertheless, where bottlenecks exist, neglecting to use demand volumes as inputs to HCM methodologies will produce results that underestimate the presence and extent of congestion. In other words, using observed volumes instead of demand volumes will likely result in inaccurate HCM results.

Where bottlenecks exist, not accounting for demand will result in underestimating the extent of congestion

Subhourly Variations in Flow

Flow rates typically vary over the course of an hour. Exhibit 4-1 shows the substantial short-term fluctuation in flow rate that can occur within an hour, on the basis of data from the approaches to an all-way STOP-controlled intersection. In this data set, the 5-min flow rate ranges from a low of 1,248 veh/h to a high of 1,764 veh/h, compared with a total peak hour entering volume of 1,516 veh. Designing the intersection to accommodate the peak hour volume would result in oversaturated conditions for a substantial portion of the hour.

Flow rates rarely remain for less than a system element's capacity, flow rates within an hour may exceed capacity, creating oversaturated conditions

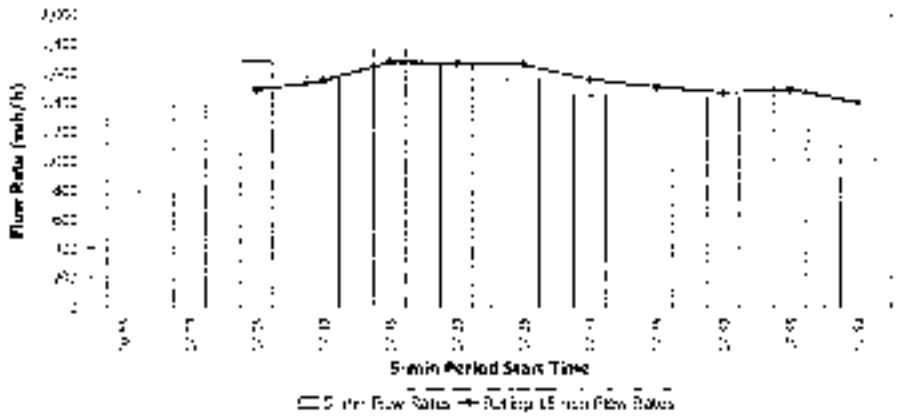

Exhibit 4-1
Relationship Between Short-Term and Hourly Flows

Source: SW 53rd Avenue at Dartmouth Street, Tigard, Oregon, 2008.

HCM analyses typically consider the peak 15 min of flow during the analysis hour. As illustrated in Exhibit 4-1, the use of a peak 15-min flow rate accommodates nearly all the variations in flow during the hour and therefore provides a good middle ground between designing for hourly volumes and designing for the most extreme 5-min flow rate.

Since inputs to HCM procedures are typically expressed in terms of hourly demands, the HCM uses the *peak hour factor* (PHF) to convert an hourly volume into a peak 15-min flow rate. Although traditionally called a "peak hour" factor, a PHF is applicable to any analysis hour, peak or off-peak. The PHF is the ratio of total hourly volume to the peak flow rate within the hour and is computed by Equation 4-1:

Peak hour factor (PHF) defined.

$$PHF = \frac{\text{Hourly volume}}{\text{Peak flow rate (within the hour)}}$$

Equation 4-1

AR0073877

If 15-min periods are used, the PHF may be computed by Equation 4-2:

Equation 4-2

$$PHF = \frac{V}{4 \times V_{15}}$$

where

PHF = peak hour factor,

V = hourly volume (veh/h), and

V_{15} = volume during the peak 15 min of the analysis hour (veh/15 min).

When the PHF is known, it can convert a peak hour volume to a peak flow rate, as in Equation 4-3:

Equation 4-3

$$v = \frac{V}{PHF}$$

where v is the flow rate for a peak 15-min period, expressed in vehicles per hour, and the other variables are as defined previously.

Equation 4-3 does not need to be used to estimate peak flow rates if traffic counts are available; however, the chosen count interval must identify the maximum 15-min flow period. Then the rate can be computed directly as 4 times the maximum 15-min count and the PHF would take the value 1.00.

Lower PHF values signify greater variability of flow, while higher values signify less flow variation within the hour. When hourly counts are used, the PHF can range from 1.00, indicating that the same demand occurs during each 15-min period of the hour, to a theoretical minimum of 0.25, indicating that the entire hourly demand occurs during the peak 15 min. PHFs in urban areas generally range between 0.80 and 0.98. PHFs over 0.95 are often indicative of high traffic volumes, sometimes with capacity constraints on flow during the peak hour. PHFs under 0.80 occur in locations with highly peaked demand, such as festivals, factories with shift changes, and venues with scheduled events.

Speed

Although traffic volumes provide a method of quantifying capacity values, speed (or its reciprocal, *travel time rate*) is an important measure of the quality of the traffic service provided to the motorist. It defines LOS for two-lane highways and urban streets.

Speed parameters.

Speed is defined as a rate of motion expressed as distance per unit of time, generally as miles per hour (mi/h). To characterize the speed of a traffic stream, a representative value must be used, because a broad distribution of individual speeds is observed in the traffic stream. Several speed parameters can be applied to a traffic stream. Among them are the following:

Average travel speed.

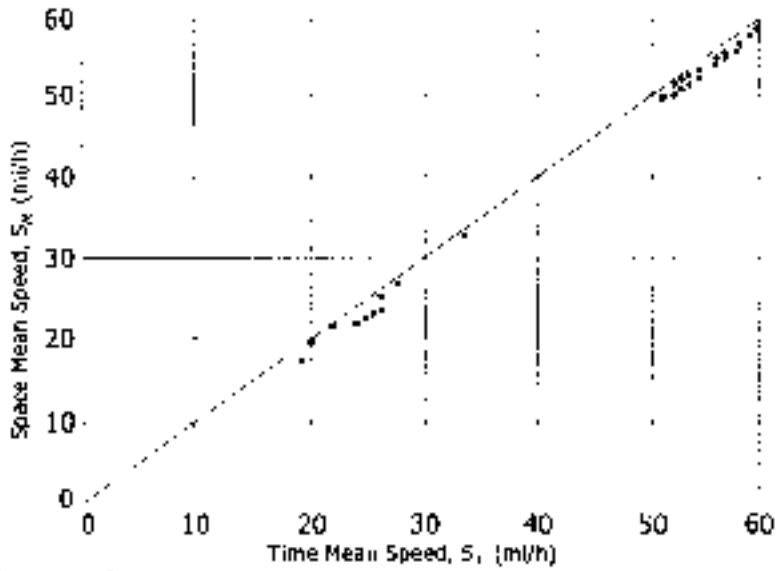
- *Average travel speed.* A traffic stream measure based on travel time observed on a known length of highway. It is the length of the segment divided by the average travel time of vehicles traversing the segment, including all stopped delay times. It is also equal to the space mean speed.

AR0073878

- *Space mean speed.* A statistical term denoting an average speed based on the average travel time of vehicles to traverse a length of roadway. It is called a space-mean speed because the average travel time weights the average by the time each vehicle spends on the defined roadway segment or space. *Space mean speed*
- *Time mean speed.* The arithmetic average of speeds of vehicles observed passing a point on a highway, also referred to as the *average spot speed*. The individual speeds of vehicles passing a point are recorded and averaged arithmetically. *Time mean speed*
- *Free-flow speed.* The average speed of vehicles on a given segment, measured under low-volume conditions, when drivers are free to drive at their desired speed and are not constrained by the presence of other vehicles or downstream traffic control devices (i.e., traffic signals, roundabouts, or STOP signs). *Free-flow speed*
- *Average running speed.* A traffic stream measure based on the observations of travel times of vehicles traversing a section of highway of known length. It is the length of the segment divided by the average running time of vehicles that traverse the segment. Running time includes only time during which vehicles are in motion. *Average running speed*

For most of the HCM procedures using speed as a service measure, average travel speed (or its equivalent, space-mean speed) is the defining parameter. On uninterrupted-flow facilities operating with undersaturated flow, the average travel speed is equal to the average running speed.

Exhibit 4-2 shows a typical relationship between time mean and space mean speeds. Space mean speed is always less than or equal to time mean speed, but the difference decreases as the absolute value of speed increases. Based on the statistical analysis of observed data, this relationship is useful because time mean speeds are typically easier to measure in the field than are space mean speeds.



Source: Drake et al. (2)

Exhibit 4-2
Typical Relationship Between Time Mean and Space Mean Speeds

AR0073879

It is possible to calculate both time mean speed and space mean speed from a sample of individual vehicle speeds. For example, three vehicles are recorded with speeds of 30, 40, and 50 mi/h. The times to traverse 1 mi are 2.0 min, 1.5 min, and 1.2 min, respectively. The time mean speed is 40 mi/h, calculated as (30 + 40 + 50)/3. The space mean speed is 38.3 mi/h, calculated as 3/[(2.0 + 1.5 + 1.2)/60].

Space mean speed is recommended for HCM analyses. Speeds are best measured by observing travel times over a known length of highway. For uninterrupted-flow facilities operating in the range of stable flow, the length may be as short as several hundred feet for ease of observation.

Density

Density is the number of vehicles occupying a given length of a lane or roadway at a particular instant. For the computations in this manual, density is averaged over time and is usually expressed as vehicles per mile (veh/mi) or passenger cars per mile (pc/mi).

Computing density

Measuring density directly in the field is difficult; it requires a vantage point for photographing, videotaping, or observing significant lengths of highway. Density can be computed, however, from the average travel speed and flow rate, which are measured more easily. Equation 4-4 is used for uncongested traffic conditions.

Equation 4-4

$$D = \frac{v}{S}$$

where

v = flow rate (veh/h),

S = average travel speed (mi/h), and

D = density (veh/mi).

A highway segment with a flow rate of 1,000 veh/h and an average travel speed of 50 mi/h would have a density of

$$D = \frac{1{,}000 \text{ veh/h}}{50 \text{ mi/h}} = 20 \text{ veh/mi}$$

Density is a critical parameter for uninterrupted-flow facilities because it characterizes the quality of traffic operations. It describes the proximity of vehicles to one another and reflects the freedom to maneuver within the traffic stream.

Roadway occupancy is frequently used as a surrogate for density in control systems because it is easier to measure (most of the through equipment such as loop detectors). Occupancy in space is the proportion of roadway length covered by vehicles, and occupancy in time identifies the proportion of time a roadway cross section is occupied by vehicles. However, unless the length of vehicles is known precisely, the conversion from occupancy to density involves some error.

AR0073880

Headway and Spacing

Spacing is the distance between successive vehicles in a traffic stream, measured from the same point on each vehicle (e.g., front bumper, front axle). Headway is the time between successive vehicles as they pass a point on a lane or roadway, also measured from the same point on each vehicle.

These characteristics are microscopic, because they relate to individual pairs of vehicles within the traffic stream. Within any traffic stream, both the spacing and the headway of individual vehicles are distributed over a range of values, generally related to the speed of the traffic stream and prevailing conditions. In the aggregate, these microscopic parameters relate to the macroscopic flow parameters of density and flow rate.

Spacing is a distance, measured in feet. It can be determined directly by measuring the distance between common points on successive vehicles at a particular instant. This generally requires costly aerial photographic techniques, so that spacing usually derives from other direct measurements. Headway, in contrast, can be measured with stopwatch observations as vehicles pass a point on the roadway.

References among density, speed and flow rate, and headway and spacing

The average vehicle spacing in a traffic stream is directly related to the density of the traffic stream, as determined by Equation 4-5:

$$\text{Density (veh/mi)} = \frac{5{,}280 \text{ ft/mi}}{\text{spacing (ft/veh)}} \quad \text{Equation 4-5}$$

The relationship between average spacing and average headway in a traffic stream depends on speed, as indicated in Equation 4-6.

$$\text{Headway (s/veh)} = \frac{\text{spacing (ft/veh)}}{\text{speed (ft/s)}} \quad \text{Equation 4-6}$$

This relationship also holds for individual headways and spacings between pairs of vehicles. The speed used is that of the second vehicle in a pair. The flow rate is related to the average headway of the traffic stream by Equation 4-7:

$$\text{Flow rate (veh/h)} = \frac{3{,}600 \text{ s/h}}{\text{headway (s/veh)}} \quad \text{Equation 4-7}$$

Relationships Among Basic Parameters

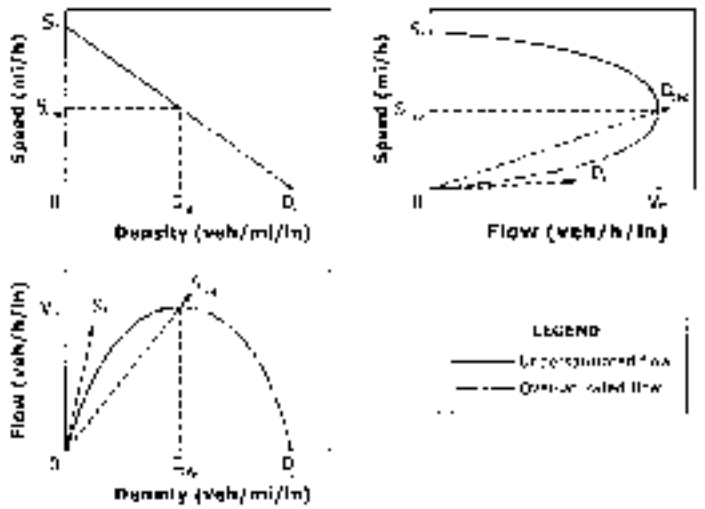
Equation 4-4 cites the basic relationship among the three parameters describing an uninterrupted traffic stream. Although the equation $v = S \times D$ algebraically allows for a given flow rate to occur in an infinite number of combinations of speed and density, there are additional relationships that restrict the variety of flow conditions that can occur in practice.

Exhibit 4-3 shows a generalized, theoretical representation of these relationships, which are the basis for the capacity analysis of uninterrupted-flow facilities. The flow–density function is placed directly below the speed–density relationship because of their common horizontal scales, and the speed–flow function is placed next to the speed–density relationship because of their common vertical scales. The speed in all cases is *space mean speed*.

AR0073881

The form of these functions depends on the prevailing traffic and roadway conditions on the segment under study and on the segment length. Although the diagrams in Exhibit 4-3 show continuous curves, it is unlikely that the full range of the functions would appear at any particular location. Real-world data usually show discontinuities, with parts of the curves not present (3). Exhibit 4-4 shows that the real-world relationship between speed and undersaturated flow consists of a section of constant speed, followed by a section of declining speed until capacity is reached, unlike the idealized parabola shown in the speed–flow curve in Exhibit 4-3. Exhibit 4-4(a) shows a relatively complete curve, while Exhibit 4-4(b) has discontinuities.

Exhibit 4-3
Generalized Relationships Among Speed, Density, and Flow Rate on Uninterrupted Flow Facilities



Source: Adapted from Ref. (3).

Exhibit 4-4
Example Freeway Speed–Flow Data

Note that the real-world speed–flow curves in Exhibit 4-4 are not the idealized parabolas indicated in Exhibit 4-3. The other relationships in Exhibit 4-3 therefore also have somewhat different shapes in the real world.

(a) I 405, Los Angeles, California (b) I 805, San Diego, California

Source: California Department of Transportation, 2008.

The curves of Exhibit 4-3 illustrate several significant points. A zero flow rate occurs under two different conditions. The first is when there are no vehicles on the segment—density is zero, and flow rate is zero. Speed is theoretical for this condition and would be selected by the first driver (presumably at a high value). This speed is represented by S_f in the graphs.

The second is when density becomes so high that all vehicles must stop—the speed and flow rate are zero because there is no movement and vehicles cannot pass a point on the roadway. The density at which all movement stops is called *jam density*, denoted by D_j in the diagrams.

AR0073882

Between these two extreme points, the dynamics of traffic flow produce a maximizing effect. As flow increases from zero, density also increases because more vehicles are on the roadway. When this happens, speed declines because of the interaction of vehicles. This decline is negligible at low and medium densities and flow rates. As density increases, the generalized curves suggest that speed decreases significantly before capacity is achieved. Capacity is reached when the product of density and speed results in the maximum flow rate. This condition is shown as the speed at capacity S_c (often called *critical speed*), density at capacity D_c (sometimes referred to as *critical density*), and maximum flow v_p.

The slope of any ray drawn from the origin of the speed–flow curve represents the inverse of density, on the basis of Equation 4-4. Similarly, a ray in the flow–density graph represents speed. As examples, Exhibit 4-3 shows the average free-flow speed and speed at capacity, as well as optimum and jam densities. The three diagrams are redundant—if any one relationship is known, the other two are uniquely defined. The speed–density function is used mostly for theoretical work; the other two are used in this manual to define LOS for freeways and multilane highways.

Exhibit 4-3 shows that any flow rate other than capacity can occur under two conditions, one low density and high speed and the other high density and low speed. The high-density, low-speed side of the curves represents oversaturated flow. Sudden changes can occur in the state of traffic (i.e., in speed, density, and flow rate). LOS A through E are drawn on the low-density, high-speed side of the curves, with the maximum-flow boundary of LOS E placed at capacity; in contrast, LOS F, which describes oversaturated and queue-discharge traffic, is represented by the high-density, low-speed part of the curves.

ADDITIONAL UNINTERRUPTED-FLOW PARAMETERS

The average headway in a lane is the reciprocal of the flow rate. Thus, at a flow of 2,400 veh/h/ln, the average headway is 3,600 s/h divided by 2,400 veh/h/ln, or 1.5 s/veh. Vehicles do not, however, travel at constant headways. Vehicles tend to travel in groups, or platoons, with varying headways between successive vehicles.

An example of the distribution of headways observed on the Long Island Expressway is shown in Exhibit 4-5. The headway distribution of Lane 3 is the most nearly uniform, as evidenced by the range of values and the high frequency of the modal value, which is the peak or the distribution curve. The distribution of Lane 2 is similar to that of Lane 3, with slightly greater scatter (range from 0.5 to 9.0 s). Lane 1 shows a much different pattern; it is more dispersed, with headways ranging from 0.5 to 12.0 s, and the frequency of the modal value is only about one-third of that for the other lanes. This indicates that the flow rate in the shoulder lane is usually lower than the flow rates in the adjacent lanes when the total flows on this segment are moderate to high.

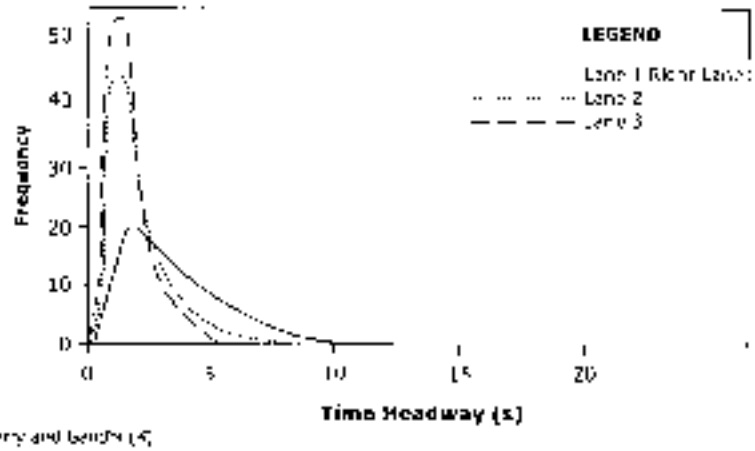
Exhibit 4-5 shows relatively few headways smaller than 1.0 s. A vehicle traveling at 60 mi/h (88 ft/s) would have a spacing of 88 ft with a 1.0-s headway, and only 44 ft with a 0.5-s headway. This effectively reduces the space between

***Headway** is the time between the vehicle fronts, while **gap** is the space between vehicles.*

AR0073883

vehicles (rear bumper to front bumper) to only 25 to 30 ft. This spacing (also called gap) would be extremely difficult to maintain.

Exhibit 4-5
Time Headway Distribution for Long Island Expressway



Source: Derzko and Sangster (4).

Drivers react to this intervehicle spacing, which they perceive directly, rather than to headway. Headway includes the length of the vehicle, which became smaller for passenger cars in the vehicle mix of the 1980s. In the 1990s and 2000s, because of the popularity of sport utility vehicles, typical vehicle lengths increased. If drivers maintain the same intervehicle spacing and car lengths continue to increase, conceivably, some decreases in capacity could result.

If traffic flow were truly random, small headways (less than 1 s) could theoretically occur. Several mathematical models have been developed that recognize the absence of small headways in most traffic streams (5).

ADDITIONAL INTERRUPTED-FLOW PARAMETERS

Basic concepts for interrupted-flow facilities, intersection control, saturation flow rate, lost time, and delay.

Interrupted flow can be more complex to analyze than uninterrupted flow because of the time dimension involved in allocating space to conflicting traffic streams. On an interrupted-flow facility, flow usually is dominated by points of fixed operation, such as traffic signals and STOP signs. These controls have different impacts on overall flow.

The operational state of traffic on an interrupted-flow facility is defined by the following measures:

- Volume and flow rate (discussed earlier in the chapter),
- Saturation flow and departure headways,
- Control variables (e.g., for signal control),
- Gaps available in the conflicting traffic streams, and
- Control delay.

Signalized Intersection Flow

The most significant source of fixed interruptions on an interrupted-flow facility is traffic signals. A traffic signal periodically halts flow for each movement or set of movements. Movement on a given set of lanes is possible only for a portion of the total time, because the signal prohibits movement

AR0073884

during some periods. Only the time during which the signal is effectively green is available for movement. For example, if one set of lanes at a signalized intersection receives a 30-s effective green time out of a 90-s total cycle, only 30/90 or 1/3 of total time is available for movement on the subject lanes. Thus, flow on the lanes can occur only for 20 min of each hour. If the lanes can accommodate a maximum flow rate of 1,500 veh/h with the signal green for a full hour, they can actually accommodate a total rate of flow of only 500 veh/h, since only one-third of each hour is available as green.

Impact of traffic signal control on maximum flow rate.

When the signal turns green, the dynamics of starting a stopped queue of vehicles must be considered. Exhibit 4-6 shows a queue of vehicles stopped at a signal. When the signal turns green, the queue begins to move. The headway between vehicles can be observed as the vehicles cross the stop line of the intersection. The first headway would be the elapsed time, in seconds, between the initiation of the green and the front wheels of the first vehicle crossing over the stop line. The second headway would be the elapsed time between the front bumpers (or wheels) of the first and second vehicles crossing over the stop line. Subsequent headways are measured similarly.

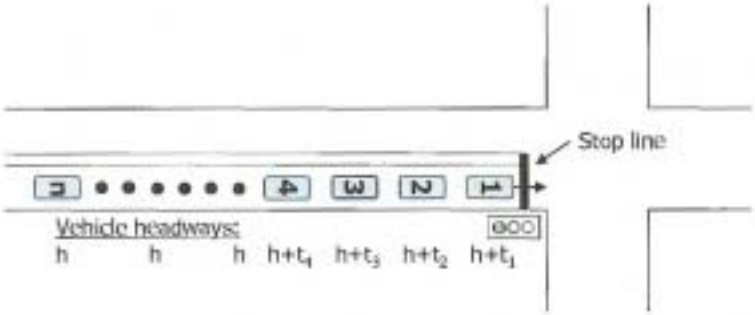


Exhibit 4-6
Acceleration Headways at a Signalized Intersection

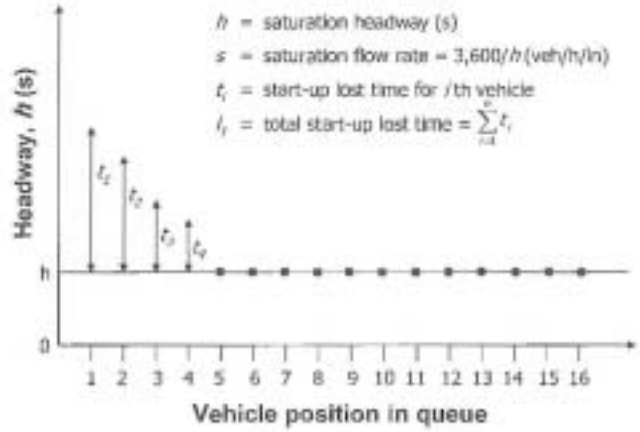
The driver of the first vehicle in the queue must observe the signal change to green and react to the change by releasing the brake and accelerating through the intersection. As a result, the first headway will be comparatively long. The second vehicle in the queue follows a similar process, except that the reaction and acceleration period can occur while the first vehicle is beginning to move. The second vehicle will be moving faster than the first as it crosses the stop line, because it has a greater distance over which to accelerate. Its headway will generally be less than that of the first vehicle. The third and fourth vehicles follow a similar procedure, each achieving a slightly lower headway than the preceding vehicle. After four vehicles, the effect of the start-up reaction and acceleration has typically dissipated. Successive vehicles then move past the stop line at a more constant headway until the last vehicle in the original queue has passed the stop line.

In Exhibit 4-6, this constant average headway, denoted as h, is achieved after four vehicles. The acceleration headways for the first four vehicles are, on the average, greater than h and are expressed as $h + t_i$, where t_i is the incremental headway for the ith vehicle due to the start-up reaction and acceleration. As i increases from 1 to 4, t_i decreases.

AR0073885

Exhibit 4-7 shows a conceptual plot of headways. The HCM recommends using the fifth vehicle following the beginning of a green as the starting point for saturation flow measurements.

Exhibit 4-7
Concept of Saturation Flow Rate and Lost Time



The value h represents the *saturation headway*, estimated as the constant average headway between vehicles after the fourth vehicle in the queue and continuing until the last vehicle that was in the queue at the beginning of the green has cleared the intersection.

Saturation flow rate.

The reference point on the vehicle used to measure headways is typically the front bumper, although front axles are sometimes used in studies that utilize tube counters to obtain the data.

Saturation flow rate is defined as the flow rate per lane at which vehicles can pass through a signalized intersection. It is computed by Equation 4-8:

Equation 4-8

$$s = \frac{3{,}600}{h}$$

where

s = saturation flow rate (veh/h), and

h = saturation headway (s).

The saturation flow rate represents the number of vehicles per hour per lane that could pass through a signalized intersection if a green signal was displayed for the full hour, the flow of vehicles never stopped, and there were no large headways. Chapter 24, Concepts: Supplemental, includes a summary of various studies of saturation flow at signalized intersections over a 25-year period.

Each time a flow is stopped, it must start again, with the first four vehicles experiencing the start-up reaction and acceleration headways shown in Exhibit 4-6. In this exhibit, the first four vehicles in the queue encounter headways longer than the saturation headway, h. The increments, t_i, are called start-up lost times.

Total start-up lost time.

The *total start-up lost time* for the vehicles is the sum of the increments, as computed by using Equation 4-9.

AR0073886

$$l_1 = \sum_{i=1}^{n} t_i$$

Equation 4-9

where

l_1 = total start-up lost time (s),

t_i = lost time for ith vehicle in queue (s), and

n = last vehicle in queue.

Each stop of a stream of vehicles is another source of lost time. When one stream of vehicles stops, safety requires some clearance time before a conflicting stream of traffic is allowed to enter the intersection. The interval when no vehicles use the intersection is called *clearance lost time*, l_2. In practice, signal cycles provide for this clearance through change intervals, which can include yellow or red-clearance indications, or both. Drivers generally cannot observe this entire interval but use the intersection during some portion of it.

Clearance lost time.

The relationship between saturation flow rate and lost times is critical. For any given lane or movement, vehicles use the intersection at the saturation flow rate for a period equal to the available green time plus the change interval minus the start-up and clearance lost times. Because lost time is experienced with each start and stop of a movement, the total amount of time lost over an hour is related to the signal timing. For instance, if a signal has a 60-s cycle length, it will start and stop each movement 60 times per hour, and the total lost time per movement will be $60(l_1 + l_2)$.

Lost time affects capacity and delay. As indicated by the relationship of cycle length to lost time, the capacity of an intersection increases as cycle length increases. However, the capacity increase can be offset somewhat by the observation that the saturation headway, h, can increase if the length of a continuous green indication increases. Capacity increases due to longer cycles are also often offset by the increase in delay that typically results from longer cycles, as discussed below. Other intersection features, such as turning lanes, can also offset the reduced capacity that results from short cycles. Longer cycles increase the number of vehicles in the queues and can cause the left-turn lane to overflow, reducing capacity by blocking the through lanes.

As indicated in Exhibit 4-8, there is a strong relationship between delay and cycle length. For every intersection there is a small range of cycle lengths that will result in the lowest average delay for motorists. Delay, however, is a complex variable affected by many variables besides cycle length.

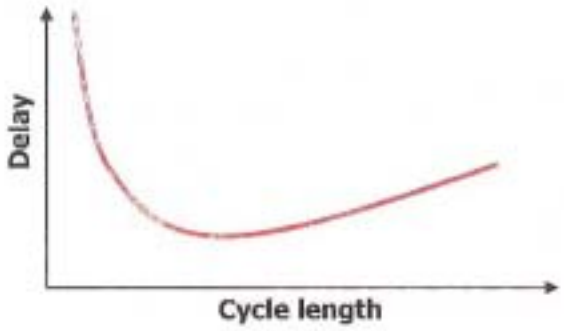


Exhibit 4-8
Generalized Cycle Length and Delay Relationship

AR0073887

STOP- and YIELD-Controlled Intersection Flow

The driver on the minor street or the driver turning left from the major street at a two-way STOP-controlled intersection faces a specific task: selecting a gap in traffic through which to execute the desired movement. The term *gap* refers to the time interval (*time gap*) and corresponding distance for a given speed (*space gap*) between the major-street vehicles entering an unsignalized intersection, measured from back bumper to front bumper. The term *gap acceptance* describes the completion of a vehicle's movement into a gap.

The capacity of a minor street approach depends on two factors:

- The distribution of available gaps in the major-street traffic stream, and
- The gap sizes required by drivers in other traffic streams to execute their desired movements.

Gap acceptance.

The distribution of available gaps in the major-street traffic stream depends on the total volume on the street, its directional distribution, the number of lanes on the major street, and the degree and type of platooning in the traffic stream. The gap sizes required by the minor-movement drivers depend on the type of maneuver (left, through, right), the number of lanes on the major street, the speed of major-street traffic, sight distances, the length of time the minor-movement vehicle has been waiting, and driver characteristics (eyesight, reaction time, age, etc.).

Critical headway.

For ease of data collection, headways (e.g., front bumper to front bumper) are usually measured instead of gaps, since only half as much data are required (i.e., only front bumper positions need to be recorded, rather than both front and back bumper positions). The *critical headway* is the minimum time interval between the front bumpers of two successive vehicles in the major traffic stream that will allow the entry of one minor-street vehicle. When more than one minor-street vehicle uses one major-street gap, the time headway between the two minor-street vehicles is called *follow-up headway*. In general, the follow-up headway is shorter than the critical headway.

The operation of roundabouts is similar to that of two-way STOP-controlled intersections. In roundabouts, however, entering drivers scan only one stream of traffic—the circulating stream—for an acceptable gap.

At an all-way STOP-controlled intersection, all drivers must come to a complete stop. The decision to proceed is based in part on the rules of the road, which suggest that the driver on the right has the right-of-way, but it is also a function of the traffic condition on the other approaches. The departure headway for the subject approach is defined as the time between the departure of one vehicle and that of the next behind it. A departure headway is considered a saturation headway if the second vehicle stops behind the first at the stop line. If there is traffic on one approach only, vehicles can depart as rapidly as the drivers can safely accelerate into and clear the intersection. If traffic is present on other approaches, the saturation headway on the subject approach will increase, depending on the degree of conflict between vehicles.

AR0073888

Delay

Control delay.

Delay is an important performance measure for interrupted-flow system elements. There are several types of delay, but *control delay*—the delay brought about by the presence of a traffic control device—is the principal service measure in the HCM for evaluating LOS at signalized and unsignalized intersections. Control delay includes delay associated with vehicles slowing in advance of an intersection, the time spent stopped on an intersection approach, the time spent as vehicles move up in the queue, and the time needed for vehicles to accelerate to their desired speed.

Other types of delay.

Other types of delay sometimes used are the following:

- *Geometric delay*. Delay caused by geometric features causing vehicles to reduce their speed in negotiating a system element (e.g., delay experienced where an arterial street makes a sharp turn, causing vehicles to slow, or the delay caused by the indirect route that through vehicles must take through a roundabout).
- *Incident delay*. The additional travel time experienced as a result of an incident, compared with the no-incident condition.
- *Traffic delay*. Delay resulting from the interaction of vehicles, causing drivers to reduce their speed below the free-flow speed.
- *Total delay*. The sum of control, geometric, incident, and traffic delay.

Number of Stops

Traffic control devices separate vehicles on conflicting paths by requiring one vehicle to stop or yield to the other. The stop causes delay and has an associated cost in terms of fuel consumption and wear on the vehicle. For this reason, information about stops incurred is useful in evaluating performance and calculating road user costs. This measure is typically expressed in terms of *stop rate*, which represents the count of stops divided by the number of vehicles served. Stop rate has units of stops per vehicle.

Stops are generally expected by motorists arriving at an intersection as a minor movement (e.g., a turn movement or a through movement on the minor street). However, through drivers do not expect to stop when they travel along a major street. Their expectation is that the signals will be coordinated to some degree such that they can arrive at each signal in succession while it is displaying a green indication for the through movement. For this reason, stop rate is a useful performance measure for evaluating coordinated signal systems.

Queuing

When demand exceeds capacity for a period of time or when an arrival headway is less than the service time (at the microscopic level) at a specific location, a queue forms (3). Queuing is both an important operational measure and a design consideration for an intersection and its vicinity. Queues that are longer than the available storage length can create several types of operational problems. A through-lane queue that extends past the entrance to a turn lane blocks access to the turn lane, keeping it from being used effectively. Similarly, a turn-lane queue overflow into a through lane interferes with the movement of

AR0073889

through vehicles. Queues that extend upstream from an intersection can block access into and out of driveways and—in a worst case—can spill back into and block upstream intersections, causing side streets to begin to queue back.

Several queuing measures can be calculated, including the average queue length, the maximum back of queue, and the maximum probable queue (e.g., a 95th percentile queue).

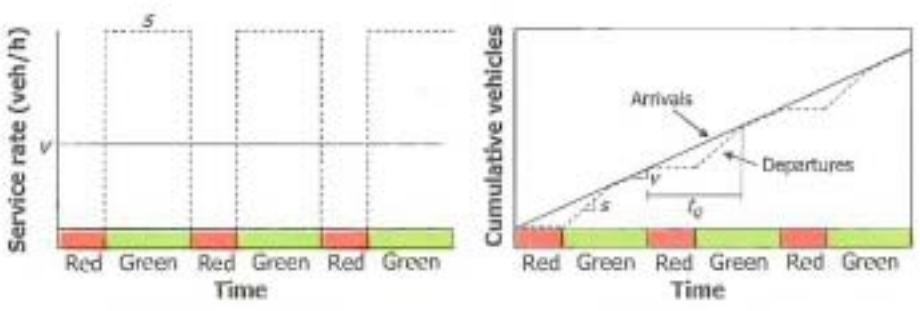
To predict the characteristics of a queuing system mathematically, it is necessary to specify the following system characteristics and parameters (4):

- Arrival pattern characteristics, including the average rate of arrival and the statistical distribution of time between arrivals;
- Service facility characteristics, including service-time average rates and the distribution and number of customers that can be served simultaneously or the number of channels available; and
- Queue discipline characteristics, such as the means of selecting which customer is next.

In oversaturated queues, the arrival rate is higher than the service rate; in undersaturated queues, the arrival rate is less than the service rate. The length of an undersaturated queue can vary but will reach a steady state with the arrival of vehicles. In contrast, the length of an oversaturated queue will never reach a steady state; it will increase with the arrival of vehicles until the arrival demand decreases.

An idealized undersaturated queue at a signalized intersection is shown in Exhibit 4-9 (3). The exhibit assumes queuing on one approach at an intersection with two signal phases. In each cycle, the arrival demand (assumed to be constant in this ideal example) is less than the capacity of the approach, no vehicles wait longer than one cycle, and there is no overflow from one cycle to the next. Exhibit 4-9(a) specifies the arrival rate, v, in vehicles per hour and is constant for the study period. The service rate, s, has two states: zero when the signal is effectively red, and up to saturation flow rate when the signal is effectively green. Note that the service rate is equal to the saturation flow rate only when there is a queue.

Exhibit 4-9
Idealized Queuing Diagram for a Two-Phase Signalized Intersection



(a) Arrival and Service Rates (b) Queue Lengths

AR0073890

Exhibit 4-9(b) diagrams cumulative vehicles over time. The horizontal line, r, in Exhibit 4-9(a) becomes a solid sloping line in Exhibit 4-9(b), with the slope equal to the flow rate. Thus, the arrival rate goes through the origin and slopes up to the right with a slope equal to the arrival rate. Transferring the service rate from Exhibit 4-9(a) to Exhibit 4-9(b) creates a different graph. During the red period, the service rate is zero, so the service is shown as a horizontal dashed line in Exhibit 4-9(b). At the start of the green period, a queue is present, and the service rate is equal to the saturation flow rate. This forms a series of triangles, with the cumulative arrival line as the top side of each triangle and the cumulative service line forming the other two sides.

Each triangle represents one cycle length and can be analyzed to calculate the time duration of the queue. It starts at the beginning of the red period and continues until the queue dissipates. Its value varies between the effective red time and the cycle length, and it is computed by using Equation 4-10:

$$t_Q = s(t_Q - r) \text{ or } t_Q = \frac{sr}{s - v} \quad \text{Equation 4-10}$$

where

t_Q = time duration of queue (s),

v = mean arrival rate (veh/h),

s = mean service rate (veh/h), and

r = effective red time (s).

The queue length (i.e., the number of vehicles in the queue, as opposed to the location of the back of the queue) is represented by the vertical distance through the triangle. At the beginning of red, the queue length is zero. It increases to its maximum value at the end of the red period. Then the queue length decreases until the arrival line intersects the service line and the queue length equals zero.

The queuing characteristics can be modeled by varying the arrival rate, the service rate, and the timing plan. In real-life situations, arrival rates and service rates are continuously changing. These variations complicate the model, but the basic relationships do not change.

CAPACITY CONCEPTS

Definition of Capacity

The *capacity* of a system element is the maximum sustainable hourly flow rate at which persons or vehicles reasonably can be expected to traverse a point or a uniform section of a lane or roadway during a given time period under prevailing roadway, environmental, traffic, and control conditions.

Vehicle capacity is the maximum number of vehicles that can pass a given point during a specified period under prevailing roadway, traffic, and control conditions. This assumes that there is no influence from downstream traffic operation, such as queues backing into the analysis point.

Person capacity is the maximum number of persons that can pass a given point during a specified period under prevailing conditions. Person capacity is

AR0073891

commonly used to evaluate public transit services, high-occupancy-vehicle lanes, and pedestrian facilities.

Prevailing roadway, traffic, and control conditions define capacity; these conditions should be reasonably uniform for any segment of a facility that is analyzed. Any change in the prevailing conditions changes a facility's capacity.

Capacity analyses examine roadway elements under uniform traffic, roadway, and control conditions. These conditions determine capacity; therefore, segments with different prevailing conditions will have different capacities.

Capacity is defined on the basis of reasonable expectancy.

Reasonable expectancy is the basis for defining capacity. That is, the stated capacity for a given system element is a flow rate that can be achieved repeatedly for peak periods of sufficient demand. Stated capacity values can be achieved on system elements with similar characteristics throughout North America. Capacity is not the absolute maximum flow rate observed on such a system element. The absolute maximum flow rate can vary from day to day and from location to location.

Persons per hour, passenger cars per hour, and vehicles per hour are measures that can define capacity, depending on the type of system element and the type of analysis. The concept of person flow is important in making strategic decisions about transportation modes in heavily traveled corridors and in defining the role of transit and high-occupancy vehicle priority treatments. Person capacity and person flow weight each type of vehicle in the traffic stream by the number of occupants carried.

Base Conditions

Base conditions defined.

Many of the procedures in this manual provide a formula or simple tabular or graphic presentations for a set of specified standard conditions, which must be adjusted to account for prevailing conditions that do not match. These standard conditions are termed *base conditions*.

Base conditions assume good weather, good and dry pavement conditions, users who are familiar with the system element, and no impediments to traffic flow. Other more specific base conditions are identified in each methodological chapter in Volumes 2 and 3.

Prevailing conditions almost always differ from the base conditions.

In most capacity analyses, prevailing conditions differ from the base conditions (e.g., there are trucks in the traffic stream, lanes are narrow). As a result, computations of capacity, service flow rate, and LOS must include adjustments. Prevailing conditions are generally categorized as roadway, traffic, or control.

Roadway Conditions

Impact of roadway conditions.

Roadway conditions include geometric and other elements. In some cases, they influence the capacity of a system element; in others, they can affect a performance measure such as speed, but not the roadway's capacity or maximum flow rate.

AR0073892

Roadway factors include the following:

- Number of lanes,
- The type of system element and its development environment,
- Lane widths,
- Shoulder widths and lateral clearances,
- Design speed,
- Horizontal and vertical alignments, and
- Availability of exclusive turn lanes at intersections.

The horizontal and vertical alignments of a highway depend on the design speed and the topography of the land on which it is constructed.

In general, as the severity of the terrain increases, capacity and service flow rates are reduced. This is significant for two-lane rural highways, where the severity of terrain can affect the operating capabilities of individual vehicles in the traffic stream and restrict opportunities for passing slow-moving vehicles.

Traffic Conditions

Traffic conditions that influence capacities and service levels include vehicle type and lane or directional distribution.

Vehicle Type

The entry of heavy vehicles—that is, vehicles other than passenger cars (a category that includes small trucks and vans)—into the traffic stream affects the number of vehicles that can be served. Heavy vehicles are vehicles that have more than four tires touching the pavement.

Trucks, buses, and recreational vehicles (RVs) are the three groups of heavy vehicles addressed by the methods in this manual. Heavy vehicles adversely affect traffic in two ways.

- They are larger than passenger cars and occupy more roadway space and
- They have poorer operating capabilities than passenger cars, particularly with respect to acceleration, deceleration, and the ability to maintain speed on upgrades.

The second impact is more critical. The inability of heavy vehicles to keep pace with passenger cars in many situations creates large gaps in the traffic stream, which are difficult to fill by passing maneuvers. Queues may also develop behind a slow-moving heavy vehicle. The resulting inefficiencies in the use of roadway space cannot be completely overcome. This effect is particularly harmful on sustained, steep upgrades, where the difference in operating capabilities is most pronounced, and on two-lane highways, where passing requires use of the opposing travel lane.

Heavy vehicles also can affect downgrade operations, particularly when downgrades are steep enough to require operation in a low gear. In these cases, heavy vehicles may operate at speeds slower than passenger cars, again forming gaps ahead and queues behind in the traffic stream.

AR0073893

Trucks cover a wide range of vehicles, from lightly loaded vans and panel trucks to the most heavily loaded coal, timber, and gravel haulers. An individual truck's operational characteristics vary on the basis of the weight of its load and its engine performance.

RVs also include a broad range campers (both self-propelled and towed), motor homes, and passenger cars or small trucks towing a variety of recreational equipment such as boats, snowmobiles, and motorcycle trailers. Although these vehicles might operate considerably better than trucks, their drivers are not professionals, which accentuates the negative impact of RVs on the traffic stream.

Intercity buses are relatively uniform in performance. Generally, urban transit buses are not as powerful as intercity buses, however. Their most severe impact on traffic results from the discharge and pickup of passengers on the roadway. For the methods in this manual, the performance characteristics of buses are considered to be similar to those of trucks.

Directional and Lane Distribution

Two traffic characteristics in addition to the distribution of vehicle types affect capacity, service flow rates, and LOS: directional distribution and lane distribution. Directional distribution has a dramatic impact on two-lane rural highway operation, where optimal conditions are achieved when the amount of traffic is roughly equal in each direction. Capacity analyses for multilane highways focus on a single direction of flow. Nevertheless, each direction of the highway is usually designed to accommodate the peak flow rate in the peak direction. Typically, morning peak traffic occurs in one direction and evening peak traffic occurs in the opposite direction. Lane distribution is another factor on multilane facilities. Typically, the right lane carries less traffic than other lanes.

Driver Population

Studies have noted that noncommuter driver populations do not display the same characteristics as do regular commuters. For example, for recreational traffic on a freeway segment, capacities have been observed to be as much as 10% to 15% lower than for commuter traffic traveling on the same segment. HCM methods include an adjustment for driver population, for system elements where driver population has made a difference in the observed capacity.

Control Conditions

For interrupted-flow facilities, the control of the time that specific traffic flows are allowed to move is critical to capacity, service flow rates, and level of service. The most critical type of control is the traffic signal. The type of control in use, signal phasing, allocation of green time, cycle length, and the relationship with adjacent control measures all affect operations.

STOP and YIELD signs also affect capacity, but in a less deterministic way. A traffic signal designates times when each movement is permitted; however, a STOP sign at a two-way stop-controlled intersection only designates the right-of-way to the major street. Motorists traveling on the minor street must stop to find gaps in the major traffic flow. The capacity of minor approaches, therefore,

AR0073894

depends on traffic conditions on the major street. An all-way STOP control requires drivers to stop and enter the intersection in rotation. Capacity and operational characteristics can vary widely, depending on the traffic demands on the various approaches.

Other types of controls and regulations can significantly affect capacity, service flow rates, and LOS. Restricted curb parking can increase the number of lanes available on a street or highway. Turn restrictions can eliminate conflicts at intersections, increasing capacity. Lane use controls can allocate roadway space to component movements and can create reversible lanes. One-way street routings can eliminate conflicts between left turns and opposing traffic.

Technology

Intelligent transportation systems.

Intelligent transportation systems (ITS) strategies aim to increase the safety and performance of roadway facilities. For this discussion, ITS includes any technology that allows drivers and traffic control system operators to gather and use real-time information to improve vehicle navigation, roadway system control, or both. Research on ITS has grown significantly but cannot be considered comprehensive in terms of evaluating ITS impacts on roadway capacity and quality of service.

Arterial ITS strategies that have been shown to improve vehicular throughput or reduce vehicular delay are adaptive signal control and traffic signal interconnection. A freeway ITS strategy, ramp metering, has demonstrated improved mainline throughput and speed, while incident management techniques have reduced the time required to identify and clear incidents, thus minimizing the time during which capacity is reduced as well as the associated delay. Variable freeway speed limits, combined with automated speed limit enforcement, also show promise but require additional study (*6*).

Other ITS strategies seek to shift demand to alternate routes or times, thus making better use of available system capacity and reducing delay on individual facilities. Techniques include parking availability signs at the entrances to downtown areas, value pricing, variable message signs, highway advisory radio, real-time travel time and incident information provided to computers and mobile phones, and real-time in-vehicle navigation systems (*6*).

Specific impacts of ITS strategies on roadway capacity and performance are discussed in Chapter 35, Active Traffic Management, where research is available to document those impacts.

ESTIMATION OF TRAFFIC FLOW PARAMETERS

Analyzing a roadway's performance involves assigning estimated values to traffic flow parameters as a function of either time or distance. There are three common approaches to estimating traffic flow parameters:

1. Deterministic models, such as those presented in the HCM;
2. Simulation models, which take a microscopic and stochastic approach to the representation of traffic flow; and

AR0073895

3. Field data observations, which attempt to measure the parameters directly by data collection and analysis.

All of these approaches can only produce estimates of the parameters of interest. Each approach involves assumptions and approximations. The three approaches are bound together by the common goal of representing field conditions accurately.

On the surface, it appears that field observations should produce the most accurate representation of traffic flow. It is difficult, however, to produce quantitative observations of some traffic phenomena in a consistent manner that avoids subjective interpretation. There are limits to the accuracy of human observation, and instrumentation of traffic flow data collection is not practical for routine field studies, except for very simple parameters such as flow rate. Field data observations require a level of effort that often exceeds the available resources. Modeling techniques have therefore been introduced as a practical, but also approximate, method of estimating required parameters. It is important that modeling techniques be based on definitions and computations that are as consistent as possible with field observations and with each other.

Vehicle trajectories are the lowest common denominator for estimating traffic flow parameters.

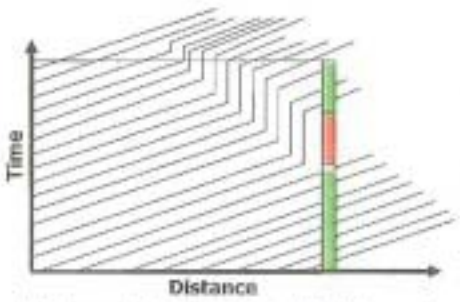
Vehicle trajectories have come to be recognized in the literature as the "lowest common denominator" for this purpose (7). Vehicle trajectories represent the "ground truth" that all measurement and analysis techniques attempt to represent. Microscopic simulation models create trajectories explicitly through algorithms that apply principles of traffic flow theory to the propagation of vehicles along a highway segment. Macroscopic deterministic models do not deal with trajectories at the same level of detail, but they attempt to produce an approximation of the results that would be obtained from trajectory analyses.

Field observations typically establish critical points along individual trajectories rather than complete trajectories.

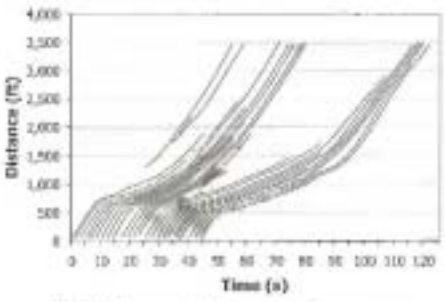
With a few exceptions involving a significant research effort, field observations are not able to create complete trajectories. Instead, they attempt to establish critical points along individual trajectories. Because of its ability to create complete trajectories, simulation modeling may be viewed as a surrogate for field data collection through which the critical points on the trajectory may be established. It is important for this purpose that the critical points be defined in a manner that promotes compatibility between the analysis techniques.

Vehicle trajectories may be represented graphically or mathematically. The graphical representation shows the position of each vehicle in time and space as it traverses a length of the highway. Typical examples of vehicle trajectory plots are shown in Exhibit 4-10.

Exhibit 4-10
Typical Examples of Vehicle Trajectory Plots



(a) Interrupted Flow on a Signalized Approach



(b) Uninterrupted Flow on a Freeway

AR0073896

Exhibit 4-10(a) depicts a classical queue accumulation and release at a signalized stop line. Exhibit 4-10(b) shows a typical freeway situation in which queuing and shock waves are caused entirely by vehicle interactions and not by traffic control devices.

There are three characteristics shown in Exhibit 4-10 that are not necessarily common to all time–space representations of vehicle trajectories:

1. Time may be shown on either the vertical or horizontal axis. Note that Exhibit 4-10(a) shows time on the vertical axis, while Exhibit 4-10(b) shows time on the horizontal axis.
2. The angular shape of the interrupted-flow trajectory curves does not represent the acceleration and deceleration in their true forms. This shape displays an approximation of the trajectory that is appropriate for some interpretations and inappropriate for others.
3. Both plots represent a single lane of operation in which each vehicle follows its leader according to established rules. Multiple-lane trajectory plots differ from single-lane plots in two ways. First, the first in, first out queue discipline can be violated in multilane situations because of overtaking. In other words, a vehicle entering a link later than its leader could leave the link earlier. Graphically, this situation is represented by trajectory lines crossing each other. Second, some vehicles might change lanes. Lane changes cannot be represented in the Exhibit 4-10 plots because distance is shown as a one-dimensional scalar quantity. Because of these complexities, multiple-lane trajectories are much harder to analyze.

While the two plots shown in Exhibit 4-10 provide good visual insights into vehicle operations, they do not support any quantitative assessments. To develop performance measures from vehicle trajectories, it is necessary to represent them mathematically, rather than visually. A mathematical representation requires the development of a set of properties that are associated with each vehicle at specific points in time and space. Because of the time-step formulation of most simulation models, it is preferable to choose time as the reference point instead of distance.

The key to producing performance measures that are comparable among different estimation techniques is the development of a set of definitions that enforce a consistent interpretation of the vehicle trajectories. The subject of trajectory-based definitions is treated in more detail in Chapter 7, Interpreting HCM and Alternative Tool Results, with additional material presented in Chapter 24, Freeway Supplemental.

AR0073897

3. PEDESTRIAN MODE

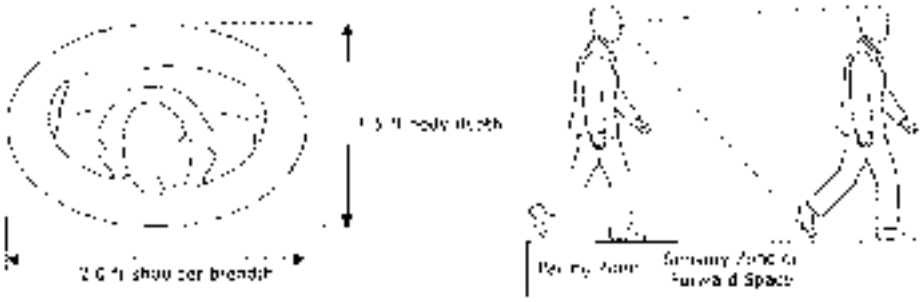
PEDESTRIAN CHARACTERISTICS

Pedestrian Space Requirements

Pedestrian facility designers use body depth and shoulder breadth for minimum space standards, at least implicitly. A simplified body ellipse of 1.5 ft by 2 ft, with a total area of 3 ft², is used as the basic space for a single pedestrian, as shown in Exhibit 4-11(a). This represents the practical minimum for standing pedestrians. In evaluating a pedestrian facility, an area of 6 ft² is used as the buffer zone for each pedestrian.

A walking pedestrian requires a certain amount of forward space. This forward space is a critical dimension, since it determines the speed of the trip and the number of pedestrians able to pass a point in a given time period. The forward space in Exhibit 4-11(b) is categorized into a personal zone and a sensory zone (8).

Exhibit 4-11
Pedestrian Body Ellipse for Standing Areas and Pedestrian Walking Space Requirement



(a) Pedestrian Body Ellipse (b) Pedestrian Walking Space Requirement

Source: Adapted from Fruin (8)

Walking Speed

Factors affecting walking speed.

Pedestrian walking speed is highly dependent on the characteristics of the walking population. The proportion of elderly pedestrians (65 years old or more) and children in the population, as well as trip purpose, affect walking speed. In a national study (9), the average walking speed of younger (age 13–60) pedestrians crossing streets was found to be significantly different from that of older pedestrians (4.74 ft/s versus 4.25 ft/s, respectively). The 15th percentile speed, the speed used in the *Manual on Uniform Traffic Control Devices (10)* for timing the pedestrian clearance interval at traffic signals, was 3.83 ft/s for older pedestrians and 4.77 ft/s for younger pedestrians. Exhibit 4-12 shows these relationships.

For flow analyses, a default free-flow speed (i.e., an average pedestrian's speed on an otherwise empty sidewalk) of 5.0 ft/s (11) is appropriate for sidewalks and walkways, on the basis of average walking speeds. In calculating pedestrian crossing rates, the 15th percentile crossing speed should be used. If no more than 20% of pedestrians are elderly, a crossing speed of 3.5 ft/s should be used (11). If elderly people constitute more than 20% of the total pedestrians, a crossing speed of 3.0 ft/s should be used. Several other factors may reduce

AR0073898

average pedestrian speed, such as grades over 5% or a high percentage of slow-walking children, and should be taken into consideration.

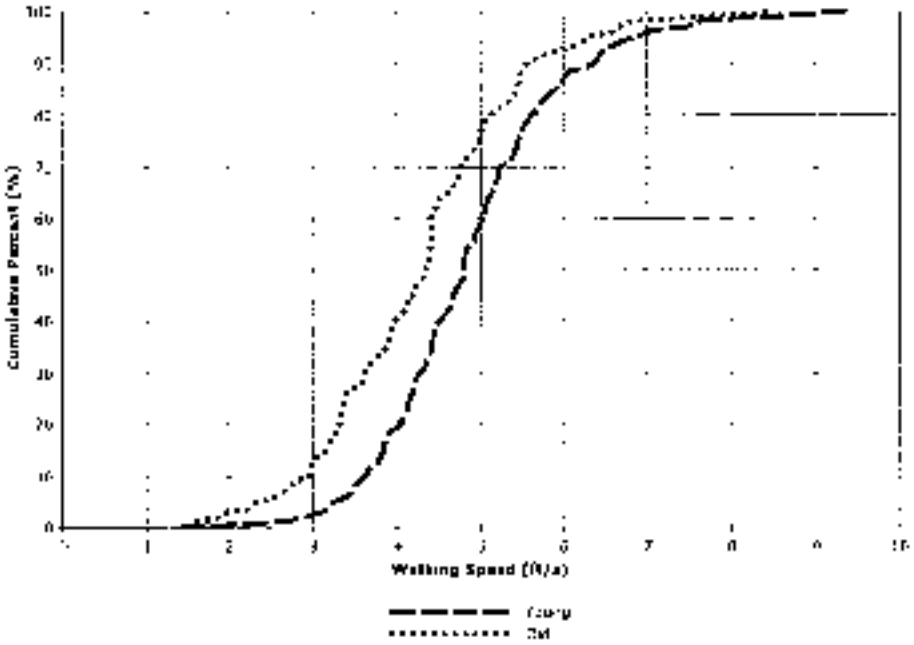


Exhibit 4-12
Observed Older and Younger Pedestrian Walking Speed Distribution at Unsignalized Intersections

Source: Adapted from *TCRP Report 112/NCHRP Report 562* (9).

Pedestrian Start-Up Time

At crosswalks located at signalized intersections, pedestrians may not step off the curb immediately when the walk indication appears, in part because of perception–reaction time and in part to make sure that no vehicles have, or are about to, move into the crosswalk's area. A pedestrian start-up time of 3 s is a reasonable midrange value to use for evaluating crosswalks at traffic signals.

PEDESTRIAN FLOW PARAMETERS

Speed, Flow, and Density Relationships

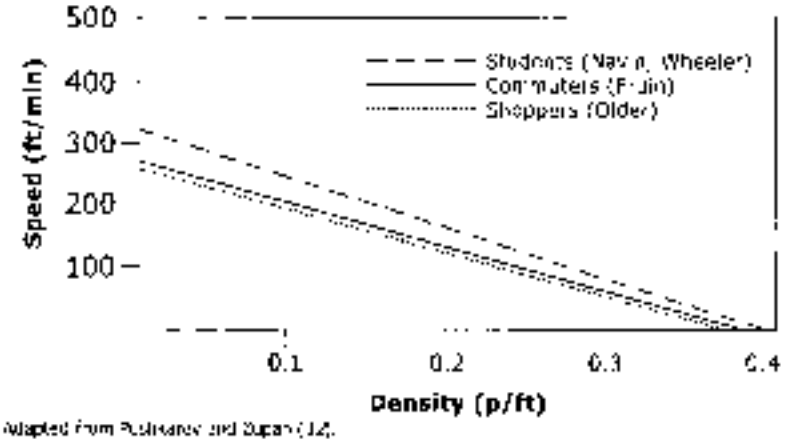
Speed–Density Relationships

The fundamental relationship between speed, density, and volume for directional pedestrian flow on facilities with no cross-flows, where pedestrians are constrained to a fixed walkway width (because of walls or other barriers), is analogous to that for vehicular flow. As volume and density increase, pedestrian speed declines. As density increases and pedestrian space decreases, the degree of mobility afforded to the individual pedestrian declines, as does the average speed of the pedestrian stream.

Exhibit 4-13 shows the relationship between speed and density for three pedestrian classes.

AR0073899

Exhibit 4-13
Relationships Between Pedestrian Speed and Density



Source: Adapted from Pushkarev and Zupan (12).

Similarities of pedestrian movement to vehicular traffic

Flow–Density Relationships

The relationship among density, speed, and directional flow for pedestrians is similar to that for vehicular traffic streams and is expressed in Equation 4-11:

Equation 4-11

$$v_{pd} = S_{ped} \times D_{ped}$$

where

v_{pd} = unit flow rate (p/min/ft),

S_{ped} = pedestrian speed (ft/min), and

D_{ped} = pedestrian density (p/ft²).

The flow variable in Equation 4-11 is the unit width flow, defined earlier. An alternative, more useful, expression uses the reciprocal of density, or space:

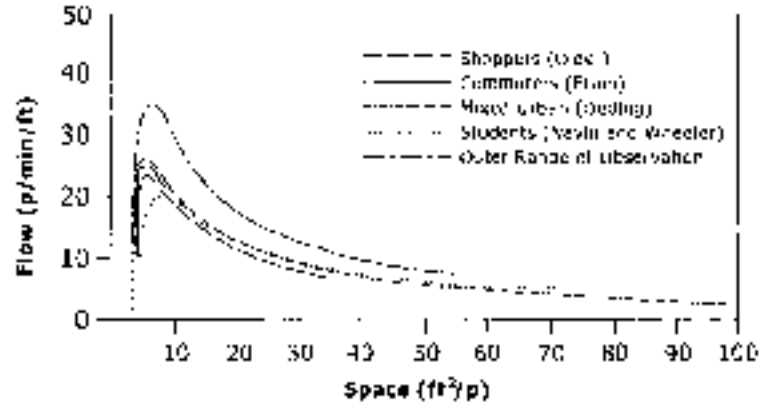
Equation 4-12

$$v_{ped} = \frac{S_{ped}}{M}$$

where M = pedestrian space (ft²/p).

The basic relationship between flow and space recorded by several researchers, as illustrated in Exhibit 4-14:

Exhibit 4-14
Relationships Between Pedestrian Flow and Space



Source: Adapted from Pushkarev and Zupan (12).

AR0073900

The conditions at maximum flow represent the capacity of the walkway facility. From Exhibit 4-14, it is apparent that all observations of maximum unit flow fall within a narrow range of density, with the average space per pedestrian varying between 5 and 9 ft²/p. Even the outer range of these observations indicates that maximum flow occurs at this density, although the actual flow in this study is considerably higher than in the others. As space is reduced to less than 5 ft²/p, the flow rate declines precipitously. All movement effectively stops at the minimum space allocation of 2 to 4 ft²/p.

These relationships show that pedestrian traffic can be evaluated qualitatively by using basic concepts similar to those of vehicular traffic analysis. At flows near capacity, an average of 5 to 9 ft²/p is required for each moving pedestrian. However, at this level of flow, the limited area available restricts pedestrian speed and freedom to maneuver.

Speed–Flow Relationships

Exhibit 4-15 illustrates the relationship between pedestrian speed and flow. These curves, similar to vehicle flow curves, show that when there are few pedestrians on a walkway (i.e., low flow levels), there is space available to choose higher walking speeds. As flow increases, speeds decline because of closer interactions among pedestrians. When a critical level of crowding occurs, movement becomes more difficult, and both flow and speed decline.

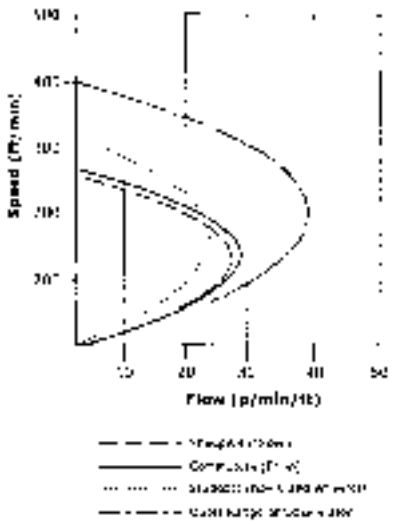


Exhibit 4-15
Relationships Between Pedestrian Speed and Flow

Source: Adapted from Pushkarev and Zupan (12).

Speed–Space Relationships

Exhibit 4-16 also confirms the relationships of walking speed and available space. The outer range of observations shown in Exhibit 4-16 indicates that at an average space of less than 15 ft²/p, even the slowest pedestrians cannot achieve their desired walking speeds. Faster pedestrians, who walk at speeds of up to 350 ft/min, are not able to achieve that speed unless the average space is 40 ft²/p or more.

AR0073901

Exhibit 4-16
Relationships Between Pedestrian Speed and Space

Flow on Urban Sidewalks and Walkways

While the fundamental relationships described above hold for pedestrians on constrained facilities with linear flow (e.g., bridges and underground passageways), they are complicated on urban sidewalks and walkways by other factors. In particular, cross-flows, stationary pedestrians, and the potential for spillover outside of the walkway affect pedestrian flows on these facilities. Quantitative research describing the effects of these factors on pedestrian flow is limited, but the effects are described qualitatively here.

Cross-flows of pedestrians entering or exiting adjacent businesses, getting on or off buses at bus stops, or accessing street furniture are typical on most urban pedestrian facilities. Where pedestrian volumes are high, these cross-flows will disrupt the speed–flow relationships described above, resulting in lower pedestrian speeds at equivalent flow rates. In addition to cross-flows, stationary pedestrians will be present on most urban pedestrian facilities, as pedestrians stop to talk, look in store windows, or pick up a newspaper from a vending machine. Stationary pedestrians reduce pedestrian flow by requiring pedestrians to maneuver around them and decreasing the available width of the walkway.

Finally, in situations where pedestrians are not physically confined within the walkway, pedestrians will often choose to walk outside of the prescribed walking area (e.g., walk in the furniture zone or street) when high densities are reached. Thus, in practice, facilities will often break down, with pedestrians spilling over into the street, before the maximum flow rate shown in Exhibit 4-14 is reached. Therefore, typical practice is to design pedestrian facilities for LOS C or D densities (13).

The result of the combination of factors described above is that many pedestrian facilities will reach effective failure at densities far less than the facility's capacity. Analysis of pedestrian facilities should take into consideration local conditions, including the presence of obstructions along the facility that contribute to cross-flows and stationary pedestrians, as well as opportunities for pedestrians to spill over onto adjacent facilities.

AR0073902

Pedestrian Type and Trip Purpose

The analysis of pedestrian flow is generally based on the mean, or average, walking speeds of groups of pedestrians. Within any group, or among groups, there can be considerable differences in flow characteristics due to trip purpose, adjacent land use, type of group, age, mobility, cognitive ability, and other factors.

Pedestrians going to and from work and using the same facilities day after day walk at higher speeds than do shoppers, as was shown in Exhibit 4-13. Older or very young persons tend to walk more slowly than do other groups. Shoppers not only tend to walk more slowly than do commuters but also can decrease the effective walkway width by stopping to window-shop and by carrying shopping bags. The analyst should adjust for pedestrian behavior that deviates from the regular patterns represented in the basic speed, volume, and density curves.

Influences of Pedestrians on Each Other

Photographic studies show that pedestrian movement on sidewalks is affected by other pedestrians, even when space is more than 40 ft²/p. At 60 ft²/p, pedestrians have been observed walking in a checkerboard pattern, rather than directly behind or alongside each other. The same observations suggest the necessity of up to 100 ft²/p before completely free movement occurs without conflicts, and that at 130 ft²/p, individual pedestrians are no longer influenced by others (*14*). Bunching or platooning does not disappear until space is about 500 ft²/p or higher.

Maintaining flow in the minor (opposing) direction.

Another issue is the ability to maintain flow in the minor direction on a sidewalk when opposed by a major pedestrian flow. For pedestrian streams of roughly equal flow in each direction, there is little reduction in the capacity of the walkway compared with one-way flow, because the directional streams tend to separate and occupy a proportional share of the walkway. However, if the directional split is 90% versus 10% and space is 10 ft²/p, capacity reductions of about 15% have been observed. This reduction results from the minor flow using more than its proportionate share of the walkway.

Opposing flows on stairways.

Similar, but more severe, effects are seen with stairways. In contrast to their behavior on a level surface, people tend to walk in lines or lanes in traversing stairs. A small reverse flow occupies one pedestrian lane (30 in.) of the stair's width. For a stair 60 in. (5 ft) wide, a small reverse flow could consume half its capacity (*13*).

Cross-flows.

A pedestrian's ability to cross a pedestrian stream is impaired at space values less than 35 to 40 ft²/p, as shown in Exhibit 4-17 (*8*). Above that level, the probability of stopping or breaking the normal walking gait is reduced to zero. Below 15 ft²/p, virtually every crossing movement encounters a conflict. Similarly, the ability to pass slower pedestrians is unimpaired above 35 ft²/p, but it becomes progressively more difficult as space allocations drop to 18 ft²/p, the point at which passing becomes virtually impossible.

AR0073903

Pedestrian Facility Characteristics

Effective Walkway Width

The lane concept used for highway analysis is frequently not applicable to pedestrian analysis, because studies have shown that pedestrians normally do not walk in organized lanes. The concept is meaningful, however, in the following situations:

- Determining how many pedestrians can walk abreast in a given walkway width—for example, in establishing the minimum sidewalk width that will permit two pedestrians to pass each other conveniently; and
- Determining the capacity of a stairway, since pedestrians will tend to organize into lanes on stairways.

In other situations, the capacity of a pedestrian facility is directly related to the width of the facility. However, not all of the facility's width may be usable, because of obstructions and pedestrians' tendencies to shy away from curbs and building walls. The portion of a pedestrian facility's width that is used for pedestrian circulation is called the *effective width*. The degree to which single obstructions, such as poles, signs, and hydrants, influence pedestrian movement and reduce effective walkway width is not extensively documented. Although a single point of obstruction would not reduce the effective width of an entire walkway, it would affect its immediate vicinity.

To avoid interference when two pedestrians pass each other, each should have at least 2.5 ft of walkway width (*12*). When pedestrians who know each other walk close together, each occupies an average width of 26 in., allowing considerable likelihood of contact due to body sway. Lateral spacing less than this occurs only in the most crowded situations.

Pedestrian Platoons

Average pedestrian flow rates are of limited usefulness unless reasonable time intervals are specified. Exhibit 4-18 illustrates that average flow rates can be misleading. The data shown are for two locations in New York City, but the pattern is generally characteristic of concentrated central business districts. Flows

AR0073904

during a 1-min interval can be more than double the rate in another, particularly at relatively low flows. Even during the peak 15-min periods, the peak 1-min flow exceeded the average flow by at least 20% and sometimes up to 75%.

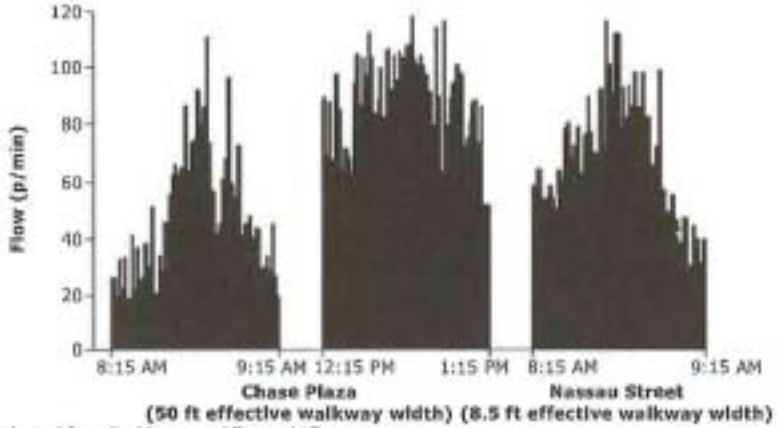

Exhibit 4-18
Minute-by-Minute Variations in Pedestrian Flow

Source: Adapted from Pushkarev and Zupan (*12*).

Depending on traffic patterns, a facility designed for average flow can afford a lower quality of flow for a portion of its pedestrian traffic. However, it is not prudent to design for extreme peak 1-min flows that occur only 1% or 2% of the time. A relevant time period should be determined through closer evaluation of the short-term fluctuations of pedestrian flow.

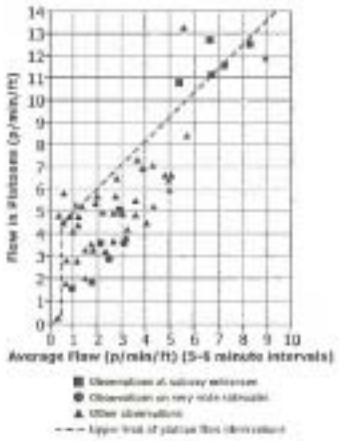
Short-term fluctuations are present in most unregulated pedestrian traffic flows because of the random arrivals of pedestrians. On sidewalks, these random fluctuations are exaggerated by the interruption of flow and queue formation caused by traffic signals. Transit facilities can create added surges in demand by releasing large groups of pedestrians in short time intervals, followed by intervals during which no flow occurs. Until they disperse, pedestrians in these types of groups move together as a platoon (Exhibit 4-19). Platoons can also form when passing is impeded because of insufficient space and faster pedestrians must slow down behind slower-moving ones.

Exhibit 4-19
Platoon Flow on a Sidewalk

The scatter diagram shown in Exhibit 4-20 compares the platoon flow rate (i.e., the rate of flow within platoons of pedestrians) with the average flow rate for durations of 5 to 6 min. The dashed line approximates the upper limit of platoon flow observations.

AR0073905

Exhibit 4-20
Relationship Between Platoon Flow and Average Flow



Source: Adapted from Pushkarev and Zupan (*12*).

CAPACITY CONCEPTS

Pedestrian Circulation Facilities

Pedestrian capacity on facilities designed for pedestrian circulation is typically expressed in terms of *space* (square feet per pedestrian) or *unit flow* (pedestrians per minute per foot of walkway width). The relationship between space and flow was illustrated in Exhibit 4-14. Capacity occurs when the maximum flow rate is achieved. Typical values for pedestrian circulation facilities are as follows:

- Walkways with random flow, 23 p/min/ft;
- Walkways with platoon flow (average over 5 min), 18 p/min/ft;
- Cross-flow areas, 23 p/min/ft (sum of both flows); and
- Stairways (up direction), 15 p/min/ft.

As shown in Exhibit 4-15, average pedestrian speeds at capacity are about half the average speed obtained under less congested conditions. As a result, pedestrian circulation facilities are typically not designed for capacity but rather for a less congested condition that achieves lower pedestrian throughput but that provides pedestrians with greater opportunity to travel at their desired speed with minimal conflicts with other pedestrians. Moreover, as described above under "Flow on Urban Sidewalks and Walkways," pedestrian facilities often break down before maximum flow rates are achieved, as a result of pedestrian spillover outside of the walkway into the furniture zone or roadway.

Pedestrian Queuing Facilities

Pedestrian capacity on facilities designed for pedestrian queuing is expressed in terms of space (square feet per pedestrian). In a queuing area, the pedestrian stands temporarily while waiting to be served. In dense, standing crowds, there is little room to move, but limited circulation is possible as the average space per pedestrian increases. Queuing at or near capacity (2 to 3 ft^2/p) typically occurs only in the most crowded elevators or transit vehicles. Queuing on sidewalks, waiting to cross at street corners, is more typically in the 3 to 6 ft^2/p range, which is still crowded but provides some internal maneuverability.

AR0073906

4. BICYCLE MODE

BICYCLE FLOW PARAMETERS

Although bicyclists are not as regimented as vehicles, they tend to operate in distinct lanes of varying widths when space is available. The capacity of a bicycle facility depends on the number of effective lanes used by bicycles. Shared-lane facilities typically have only one effective lane, but segregated facilities such as bicycle lanes, shoulder bikeways, pathways, and cycle tracks may have more than one effective lane, depending on their width. When possible, an analysis of a facility should include a field evaluation of the number of effective lanes in use. When this is not possible, or when future facilities are planned, a standard width for an effective bicycle lane is approximately 4 ft (15). The American Association of State Highway and Transportation Officials recommends that off-street bicycle paths be 10 ft wide (15).

Research demonstrates that three-lane bicycle facilities operate more efficiently than two-lane bicycle facilities, affording considerably better quality of service to users (16). The improved efficiency is due primarily to increased opportunities for passing and for maneuvering around other bicyclists and pedestrians. This reinforces the value of determining the number of effective lanes as the principal input for analyzing a bicycle facility.

A study that compared mean bicycle speeds with bicycle flow rates over 5-min periods found at most a minor effect of flow rates on speed, for flow rates ranging from 50 to 1,500 bicycles/h. When the analysis focused on platoons of bicycles with headways less than 5 s, bicycle speeds trended slightly lower as flow rates increased (17).

Most bicyclists travel on facilities that are shared with automobiles. In these circumstances, bicycle flow is significantly affected by the characteristics of surrounding automobile flow. Bicyclists often must wait behind queues of automobiles. Even where bicyclists may pass such queues, they are often forced to slow because the available space in which to pass is too constrained to allow free-flow speeds to occur.

Data collected for more than 400 adult bicyclists riding on uninterrupted multiuse segments showed an average speed of 12.8 mi/h (16). However, the speed of an individual bicyclist varies considerably from this average on the basis of trail conditions, age, fitness level, and other factors. Exhibit 4-21 shows how bicyclist speed varies with age, on the basis of Danish data. Data are for typical bicycles on flat terrain.

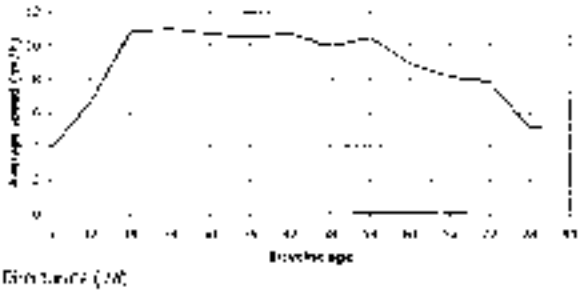


Exhibit 4-21
Age Effects on Bicyclist Speed

Source: Danish Road Directorate (18).

AR0073907

Flow rates of bicyclists typically vary over the course of an hour. As described above for automobiles, HCM analyses typically consider the peak 15 min of flow during the analysis hour. Because inputs to HCM procedures are typically expressed in terms of hourly demands, the HCM uses the PHF, shown by Equation 4-1, to convert an hourly volume into a peak 15 min flow rate. Data for bicycles on eight trails, recorded over three separate time periods for each trail, showed PHFs ranging from 0.70 to 0.99, with an average of 0.85 (*18*).

CAPACITY CONCEPTS

Because service quality deteriorates at flow levels well below capacity, the concept of capacity has little utility in the design and analysis of bicycle paths and other facilities. Capacity is rarely observed on bicycle facilities. Values for capacity, therefore, reflect sparse data, generally from Europe and generally extrapolated from flow rates over time periods substantially less than 1 h.

One study reported capacity values of 1,600 bicycles/h/lane for two-way bicycle facilities and 3,200 bicycles/h/ln for one-way facilities. Both values were for exclusive bicycle facilities operating under uninterrupted-flow conditions (*19*). Other studies have reported values in the range of 1,500 to 5,000 bicycles/h/ln for one-way uninterrupted-flow facilities (*76*).

Danish guidelines suggest that bicycle capacity is normally only relevant at signalized intersections in cities and that a rule of thumb for the capacity of a two-lane cycle track is 2,000 bicycles/h under interrupted-flow conditions (i.e., 1,000 bicycles/h/ln) (*20*). The HCM recommends a saturation flow rate of 2,000 bicycles/h/ln for a one-direction bicycle lane under interrupted-flow conditions, which is equivalent to a capacity of 2,000 bicycles/h/ln when the bicycle lane receives a green indication during 50% of the signal cycle.

DELAY

Delay is an important performance measure for bicyclists on interrupted-flow system elements. This is true because delay increases travel time and because the physical exertion required to accelerate a bicycle makes stopping or slowing undesirable and tiring. The difficulty involved in stopping and starting a bicycle often makes it appropriate to assess not only the control delay incurred by bicyclists but also the number of stops that bicyclists are required to make to traverse a facility. For instance, a facility with stop signs every several hundred feet will require bicyclists to stop frequently and thus will provide lower capacity and quality of service to users.

AR0073908

5. TRANSIT MODE

BUS SPEED PARAMETERS

Material in this section generally refers to buses but is also applicable to streetcars and light rail vehicles operating on urban streets, except where specifically stated otherwise.

Bus speeds on urban streets are influenced by the same factors that influence automobile speeds, particularly the delay caused by traffic signals and other forms of intersection control. As heavy vehicles, buses accelerate and decelerate more slowly than passenger cars. In addition, there are many bus-specific factors that influence speed, involving operations, vehicle, roadway, and passenger characteristics. These factors are described below.

Operations Characteristics

Stop Spacing

Unlike other urban street users, most transit vehicles (except for express buses) stop periodically so that passengers may board and alight. Each stop introduces up to four forms of delay:

- *Acceleration and deceleration delay*, as a bus slows down approaching a stop and returns to its running speed after departing the stop;
- *Passenger service time*, while the bus is stopped and passengers are actively boarding and alighting;
- *Traffic signal delay*, when a bus arrives at a curb-side stop (i.e., a bus stop immediately prior to an intersection) during the green interval, serves its passengers, and then experiences delay while waiting for the traffic signal to turn green again before proceeding; and
- *Reentry time*, when a bus stops out of the curb travel lane and then must wait for a gap in traffic before it can reenter the lane.

Increasing the stop spacing reduces the number of occurrences of these types of delay, which results in a net increase in speeds. (Passenger service times may increase, though, as passengers activity is concentrated at fewer stops.) For example, five bus rapid transit routes in Los Angeles that have stop spacings ranging from 2/3 to 1 mi and no other contributing factors (e.g., transit signal priority) achieved travel time reductions of 17% to 29% compared with the previous local bus service (*21*).

The ability to increase stop spacing depends on many factors, including the surrounding pedestrian environment, the locations of transit trip generators and transfer opportunities, and driveway and curb parking locations (*15*).

Fare Payment

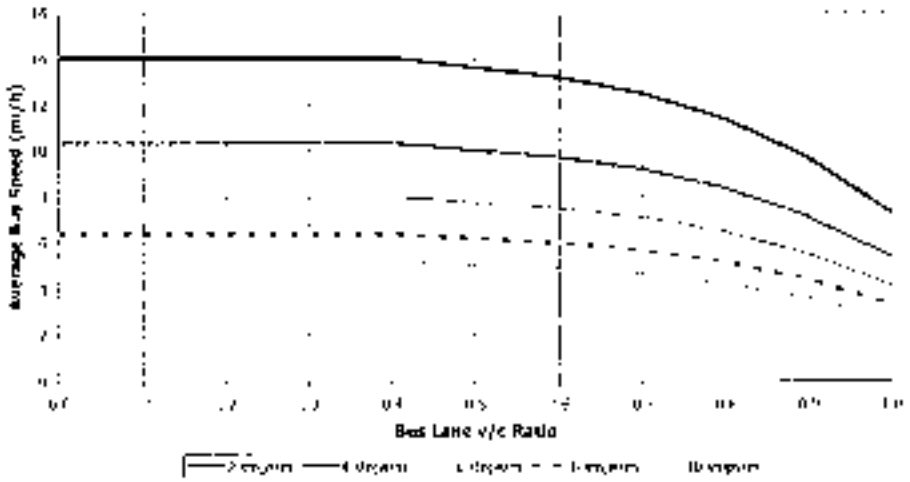
The time required for passengers to pay a fare affects the passenger service rate at stops. The average base amount of time needed to board a high-floor bus with no or prepaid (e.g., bus pass or free transfer) fare payment is 2.5 s/passenger. The various types of fare payment methods (e.g., cash, tickets, tokens, magnetic-stripe cards, smart cards) have service times associated with them that increase the service time by up to 1.8 s/passenger, on average, above the base level. (*13*)

AR0073909

Service Planning and Scheduling

Bus speeds along an urban street decline when 50% or more of a bus lane's hourly capacity is utilized, as illustrated in Exhibit 4-22. As the number of buses using a bus lane increases, there is a greater probability that one bus will delay another bus, either by using all available space at a bus stop or by requiring bus passing and weaving maneuvers. At a volume-to-capacity (v/c) ratio of 1.0, bus speeds are approximately half of what can be achieved at v/c ratios under 0.5 (13).

Exhibit 4-22
Illustrative Bus Speed Relationship to Bus Lane v/c Ratio



Notes: Assumes 30 s cycle times, downtown bus lane with right-turn lanes, and typical signal timing.
Source: *TCRP Report 100: Transit Capacity and Quality of Service Manual (13).*

On buses where demand exceeds seating capacity, causing some passengers to stand, more passenger service time is required at stops, because standing passengers must push toward the back of the bus to allow other passengers to board and because alighting passengers take longer to get to a door.

Vehicle Characteristics

Low-floor buses can reduce passenger service time by eliminating the need to ascend and descend steps. These buses are particularly useful for routes frequently used by the elderly, persons with disabilities, or persons with strollers or bulky carry-on items. Wide bus doors also allow more passengers to board and alight simultaneously (13).

Roadway Characteristics

Transit Preferential Treatments

Refer to TCRP Report 118 (22) for illustrations and guidance on appropriate locations for transit preferential treatments.

Transit preferential treatments, both geometric and operational, give transit vehicles a travel time advantage over other roadway users. Common types of treatments include the following.

- *Exclusive bus lanes.* One or more lanes on a street that are reserved on a full- or part-time basis for the exclusive use of buses. Exclusive bus lanes partially or entirely eliminate interactions with automobiles and other roadway users that can slow down a bus. With typical signal timing, bus

AR0073910

lanes typically provide a 10- to 15-min/mi speed advantage over mixed-traffic operations (13).

- *Queue jumps.* A short bus lane section (often shared with a right-turn lane), in combination with an advance green indication for the lane, that allows buses to move past a queue of cars at a signal. These typically reduce bus delay at a signalized intersection by 5% to 15% (22).
- *Curb extensions.* An extension of the sidewalk to the edge of the travel or bicycle lane (e.g., by removing on-street parking). Curb extensions allow buses to stop in the travel lane and thus to avoid delay when they leave the stop. At the range of curb volumes appropriate for curb extensions (under 500 veh/h), they can save buses up to 5 s of delay per stop on average (22).
- *Traffic signal priority.* Changes to traffic signal timing to favor bus operations. These include *passive* (pretimed) changes—for example, to set a street's signal progression to favor buses rather than cars (as is done at downtown Ottawa). *Active* strategies adjust signal timing in real time to the arrival of a bus—for example, to extend a green interval to accommodate a bus arriving late in the interval or to shorten the red interval to get a stopped bus under way sooner. *Real-time* strategies consider both automobile and bus arrivals at a single intersection or a network of intersections. *Traffic signal priority* is rarely used for buses because of signal system operations and safety issues but is a feature of some light rail routes. Systems of intersections equipped with traffic signal priority have typically reduced transit travel times by 5% to 15%, with a range of reported values of 0% to 40% (13, 22).
- *Turn restriction exemption.* Buses are allowed to make turns at locations where other vehicles are not allowed to. This treatment allows buses to travel more direct routes; the time saved depends on the length of and the delay associated with the alternate route (13).

Bus Stop Location

Buses can stop in the travel lane (*on line*) or out of the travel lane (*off line*), for example, in a bus pullout. Off-line stops require buses to find a gap in traffic when they reenter the travel lane, which generates reentry delay that can average 1 to 15 s with random vehicle arrivals, depending on the traffic volume in the curb lane. Some jurisdictions have passed yield-to-bus laws that require motorists to allow a bus back into traffic. These laws can reduce or eliminate reentry delay, depending on the degree of motorist compliance (13).

Bus stops can be located before an intersection (*near side*), after an intersection (*far side*), or between intersections (*midblock*). The interaction of right-turning vehicles and buses at near side stops can create delays. Buses are also more likely to get caught by a red signal after serving passengers at a near-side stop than at a far-side stop. On the other hand, buses using off-line far-side stops may cause traffic to back up behind the bus into the intersection. Refer to the *Transit Capacity and Quality of Service Manual* (13) for a full list of the advantages and disadvantages of each type of stop location.

AR0073911

Passenger Characteristics

Passenger Distribution

The distribution of boarding passengers among bus stops affects the passenger service time of each stop. If passenger boardings are concentrated at one stop along a street, that street's bus capacity will be lower than if boardings were more evenly distributed. Bus stop capacity decreases as average passenger service time increases, and the bus capacity of a street is constrained by the lowest bus stop capacity along the street. With a lower capacity, it takes fewer scheduled buses in an hour for interactions between buses to begin to affect bus speeds. However, if boardings are concentrated because of a consolidation of bus stops, the net effect will be improved speed and a reduced number of stops, which will offset the increased passenger service time at the remaining stops.

Strollers, Wheelchairs, and Bicycles

Passenger service times are longer for passengers with strollers or using wheelchairs, particularly with high-floor buses when a lift must be deployed. A passenger using a bicycle rack mounted to the bus will also cause service time to increase, except when other passengers are still being served after the bicycle has been secured. In many cases, these events are sufficiently infrequent to be indistinguishable from the normal variation in passenger demands and service times at a bus stop.

CAPACITY CONCEPTS

Differences Between Transit and Automobile Capacity

Transit capacity is different from highway capacity: it deals with the movement of both people and vehicles, it depends on the size of the transit vehicles and how often they operate, and it reflects the interaction of passenger traffic and vehicle flow. Transit capacity depends on the operating policy of the transit agency, which specifies service frequencies and allowable passenger loadings. Accordingly, the traditional concepts applied to highway capacity must be adapted and broadened.

Two key characteristics differentiate transit from the automobile in terms of availability and capacity. Although the automobile has widespread access to roadway facilities, transit service is available only in certain locations and during certain times. Roadway capacity is available 24 h/day once constructed, but transit passenger capacity is limited by the number of transit vehicles operated at a given time.

Throughout the transit sections of the HCM, a distinction is made between vehicle and person capacity. *Vehicle capacity* reflects the number of transit units (buses or trains) that pass a given location during a given time period. Thus, bus vehicle capacity is most closely analogous to automobile capacity. *Person capacity* reflects the number of people that can be carried past a given location during a given time period under specified operating conditions, without unreasonable delay, hazard, or restriction, and with reasonable certainty.

AR0073912

On-street bus capacity has a two-dimensional nature. It is possible to operate many buses, each carrying only a few passengers. Whether the buses are full or empty, a larger number of buses can have a negative impact on LOS in terms of highway capacity. Alternatively, only a few buses could operate, each overcrowded. This represents a poor quality of service from the passenger perspective, and long waiting times would detract from user convenience.

Vehicle Capacity

Vehicle (bus) capacity is commonly determined for three locations along an urban street: individual loading areas (berths) at bus stops, individual bus stops, and an urban street facility, as illustrated in Exhibit 4-23. Each location directly influences the next. The vehicle capacity of a bus stop is controlled by the vehicle capacities of the loading areas, and the vehicle capacity of the urban street facility is controlled by the vehicle capacity of the critical stop within the facility.

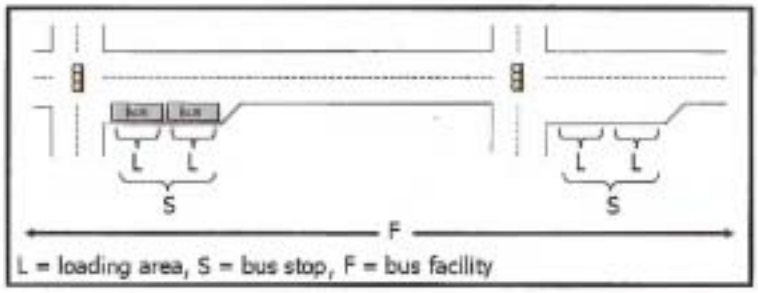


Exhibit 4-23
Bus Loading Areas, Stops, and Facilities

Source: *TCRP Report 100: Transit Capacity and Quality of Service Manual (13).*

Loading Area Capacity

The main elements that determine loading area capacity are dwell time, dwell time variability, traffic signal timing, failure rate, and clearance time (*13*):

- *Dwell time* is the sum of passenger service time and the time to open and close the bus doors.
- *Dwell time variability* accounts for the fact that buses do not stop for the same amount of time at a stop because of fluctuations in passenger demand for buses and routes.
- *Traffic signal timing* affects the time available in an hour for buses to enter and exit a bus stop. In addition, the length of red in relation to the dwell time of a bus affects vehicle capacity: if passenger movements have finished but the vehicle must wait for the traffic signal to turn green, vehicle capacity will be less than if the bus can leave immediately so that another bus can use the loading area.
- *Failure rate* is a design input and is the probability that one bus will arrive at a bus stop only to find all loading areas already occupied.
- *Clearance time* is an interval after a bus is ready to depart during which the loading area is not available for use by a following bus. Part of this time is fixed, consisting of the time for a bus to start up and travel its own length, clearing the stop. For off-line stops, a second component of clearance time is the reentry time discussed previously.

AR0073913

Bus Stop Capacity

Bus stops consist of one or more loading areas. When a bus stop consists of a single loading area, its capacity is equivalent to the loading area capacity. However, when a bus stop consists of multiple loading areas, the number of loading areas and the design of the loading areas also influence its capacity.

Effective loading areas.

The vast majority of on-street bus stops are *linear* bus stops, where the first bus to arrive occupies the first loading area, the second bus occupies the second loading area, and so on. Each additional linear loading area at a bus stop is less efficient than the one before it for three reasons:

1. The rear loading areas will be used less often than the first loading area;
2. Not knowing which loading area their bus will stop at, passengers may have to walk down the line of buses to get to their bus, increasing its passenger service time; and
3. Depending on how closely buses stop behind the bus in front and the buses' ability to pass one another, a bus may not be able to leave its loading area until the bus in front of it departs.

Efficiency drops significantly above three loading areas. Efficiency is also affected by whether the bus stop is on-line or off-line and by whether buses arrive irregularly (the usual situation) or are operated in groups of two or three buses (*platoons*) that act like cars of a train (*13*).

Bus Facility Capacity

Bus facility capacity is constrained by the capacity of the critical bus stop along the facility. The critical bus stop is usually the bus stop with the longest dwell time; however, high vehicular traffic volumes (particularly turning volumes) along with conflicting pedestrian volumes can combine to make a particular bus stop the critical stop. The impact of vehicular traffic on capacity also depends on the location of a particular bus stop, with near-side stops being affected more than far-side stops, and on whether buses operate in mixed traffic or in a bus lane (*13*).

Exhibit 4-24 summarizes the elements that determine bus facility capacity.

Person Capacity

For HCM analysis purposes, person capacity is typically calculated only at the facility level.

Person capacity is determined by three main factors (*13*):

1. *Vehicle capacity,* which determines the maximum number of buses that can be scheduled to use the bus facility over the course of an hour;
2. *Agency policy,* which sets loading standards for buses and determines how frequently buses operate (which is usually less than the maximum possible frequency); and
3. *Passenger demand characteristics,* reflected by a PHF.

There are many ways to measure the performance of a transportation facility or service—and many points of view that can be considered in deciding which measurements to make. The agency operating a roadway, automobile drivers, pedestrians, bicyclists, bus passengers, decision makers, and the community at large all have their own perspectives on how a roadway or service should perform and what constitutes "good" performance. As a result, there is no one right way to measure and interpret performance. **Chapter 5, Quality and Level-of-Service Concepts,** presents the concepts that the *Highway Capacity Manual* (HCM) uses to describe performance from the traveler point of view in a way that is designed to be useful to roadway operators, decision makers, and members of the community.

Quality of service describes how well a transportation facility or service operates from the traveler's perspective. *Level of service* (LOS) is a qualitative stratification of a performance measure or measures that represent quality of service. The LOS concept facilitates the presentation of results through the use of a familiar A (best) to F (worst) scale. LOS is defined by one or more service measures that both reflect the traveler perspective and are useful to operating agencies.

Three overarching concepts—quality of service, LOS, and service measures—are the subjects of this chapter.

AR0073921

2. QUALITY OF SERVICE

Quality of service defined.

Quality of service describes how well a transportation facility or service operates from a traveler's perspective. Quality of service can be assessed in a number of ways. Among them are directly observing factors measurable by and important to travelers (e.g., speed or delay), surveying travelers, tracking complaints and compliments about roadway conditions, forecasting traveler satisfaction by using models derived from past traveler surveys, and observing services not directly perceived by travelers (e.g., average time to clear an incident) that affect measures they can perceive (e.g., speed or arrival time at work).

Factors that influence traveler perceived quality of service have been found to include

- Travel time, speed, and delay,
- Number of stops incurred,
- Travel time reliability,
- Maneuverability (e.g., ease of lane changing, percent time-spent-following other vehicles),
- Comfort (e.g., bicycle and pedestrian interaction with and separation from traffic; transit vehicle crowding; ride comfort);
- Convenience (e.g., directness of route, frequency of transit service);
- Safety (actual or perceived);
- User cost;
- Availability of facilities and services;
- Facility aesthetics; and
- Information readability (e.g., highway wayfinding signage, transit route and schedule information).

The HCM provides tools to measure the multimodal operational aspects of quality of service.

The HCM's scope, measuring the multimodal performance of highway and street facilities, is narrower than the list of quality of service aspects listed above. As discussed in Chapter 1, HCM User's Guide, companion documents to the HCM address highway safety, roadway design, and wayfinding signage, among other topics. The HCM focuses particularly on the travel time, speed, delay, maneuverability, and comfort aspects of quality of service, although a limited number of the HCM's performance measures address some of the other aspects listed above. Federal Strategic Highway Research Program 2 research that was programmed at the time this manual was written may add measures of travel time reliability to the HCM in the future.

LOS is an important tool used by the HCM to define quality of service.

The HCM provides a variety of performance measures in Volumes 2 and 3 to assess the quality of service of transportation system elements. These measures can be directly observed in the field or estimated from things observable in the field. LOS is the stratification of quality of service and is further described in the next part of this chapter.

AR0073922

3. LEVEL OF SERVICE

DEFINITION

LOS defined

LOS is a quantitative stratification of a performance measure or measures that represent quality of service. The measures used to determine LOS for transportation system elements are called *service measures*. The HCM defines six levels of service, ranging from A to F, for each service measure, or for the output from a mathematical model based on multiple performance measures. LOS A represents the best operating conditions from the traveler's perspective and LOS F the worst. For cost, environmental impact, and other reasons, roadways are not typically designed to provide LOS A conditions during peak periods, but rather some lower LOS that reflects a balance between individual travelers' desires and society's desires and financial resources. Nevertheless, during low-volume periods of the day, a system element may operate at LOS A.

LOS is analyzed on an A–F scale. LOS A represents the best conditions from a traveler's perspective.

USAGE

LOS is used to translate complex numerical performance results into a simple A–F system representative of travelers' perceptions of the quality of service provided by a facility or service. The LOS letter result hides much of the complexity of facility performance. This feature is intended to simplify decision making on whether facility performance is generally acceptable and whether a future change in performance is likely to be perceived as significant by the general public. The language of LOS provides a common set of definitions that transportation engineers and planners can use to describe operating conditions; however, it is up to local policymakers to decide the appropriate LOS for a given system element in their community. One reason for the widespread adoption of the LOS concept by agencies is the concept's ability to communicate roadway performance to nontechnical decision makers. However, LOS has other strengths and weaknesses, described below, that both analysts and decision makers need to be mindful of.

LOS is a useful and widely adopted tool for communicating roadway performance to laypersons and decision makers. However, one should also be mindful of its weaknesses.

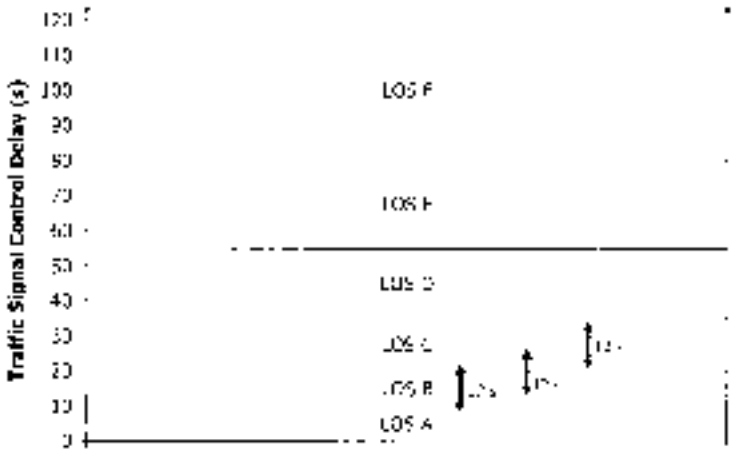
Step Function Nature of LOS

LOS is a step function. An increase in average control delay of 12 s at a traffic signal, for example, may result in no change in LOS, a drop of one level, or even a drop of two levels, depending on the starting value of delay, as illustrated in Exhibit 3-1.

From a traveler perception standpoint, the condition shown in Exhibit 3-1 is not necessarily inconsistent. A change of LOS indicates that roadway performance has transitioned from one given range of traveler-perceivable conditions to another range, while no change in LOS indicates that conditions have remained within the same performance range as before. Service measure values indicate where conditions lie within a particular performance range. However, because a small change in a service measure, or the output from a mathematical model based on multiple performance measures, can sometimes result in a change from one LOS to another, the LOS result could imply a more significant effect than actually occurred.

AR0073923

Exhibit 5-1
Example of the Step Function Nature of LOS



Identical changes in the service measure value may result in no change in LOS or a change of one or more levels of service, depending on how close the starting value is to a LOS threshold.

Use of LOS can be a particularly sensitive issue when agencies define their operational performance standards solely by using LOS. However, the definition of a level standard, whether numerically or as a LOS letter, always brings the possibility that a small change in performance can trigger the need for potentially costly improvements.

Defining performance standards on the basis of LOS for any facet (numerical value) means that even changes in performance can sometimes result in the standard being exceeded, when a facility is already operating close to the standard.

Variability of the Inputs to LOS

Although computer software that implements HCM methodologies can sometimes report results to many decimal places, three major sources of uncertainty influence service measure values and, thus, the LOS result:

1. The models used to estimate service measure values have confidence intervals associated with their outputs;
2. These models, in turn, rely on the output of other models that have their own associated confidence intervals; and
3. The accuracy of input variables, such as demand flow rate, is taken to be absolute when, in fact, there is a substantial stochastic variation around the measured values.

Chapter 7, Interpreting HCM and Alternative Tool Results, discusses sources of uncertainty and their impacts on analysis results in more detail.

Thus, any reported service measure value, whether resulting from an HCM methodology, an alternative tool, or even field measurement, potentially has a fairly wide range associated with it in which the "true" value actually lies. The LOS concept helps to downplay the implied accuracy of a numeric result by presenting a range of service measure results as being reasonably equivalent from a traveler's point of view. Nevertheless, the same variability issues also mean that the "true" LOS value may be different from the one predicted by a methodology. In addition, for any given set of conditions, different travelers may perceive their LOS to be different from one another, as well as different from the LOS estimated by an HCM method. One way of thinking about reported service measure values and the corresponding LOS result is that they are the statistical "best estimates" of conditions and aggregate traveler perceptions.

Models provide a best estimate of service measure values, but the "true" value may lie within a confidence interval range above or below the estimated value.

AR0073924

Beyond LOS F

The HCM does not subdivide LOS F, but several measures are available to describe the severity of a LOS F condition.

The HCM uses LOS F to define operations that have either broken down (i.e., demand exceeds capacity) or have exceeded a specified service measure value (or combination of service measure values) that most users would consider unsatisfactory. However, particularly for planning applications where different alternatives may be compared, analysts may be interested in knowing just how bad the LOS F condition is. Several measures are available to describe numerically, or in combination, the severity of a LOS F condition:

- *Demand to capacity ratio* describes the extent to which capacity is exceeded during the analysis period (e.g., by 1%, 15%, etc.).
- *Duration of LOS F* describes how long the condition persists (e.g., 15 min, 1 h, 3 h).
- *Spatial extent* measures describe the areas affected by LOS F conditions. These include measures such as the back of queue and the identification of the specific intersection approaches or system elements experiencing LOS F conditions.

Separate LOS Reporting by Mode and System Element

LOS is reported separately by mode for a given system element.

LOS is reported separately for each mode operating on a given system element (although some other modes, such as large trucks, recreational vehicles (RVs), and motorcycles are currently considered members of the automobile mode for HCM analysis purposes). Each mode's travelers have different perspectives and potentially experience very different conditions while traveling along a particular roadway. Using a blended LOS risks overlooking quality of service deficiencies for nonautomobile travelers that discourage the use of those modes, particularly if the blended LOS is weighted by the number of modal travelers. Other measures, such as person delay, can be used when an analysis requires a combined measure.

Identical values of some service measures (e.g., delay) can produce different LOS results, depending on the system element to which the service measure is applied. The TRB Committee on Highway Capacity and Quality of Service (HCQS Committee) believes that travelers' expectation of performance varies at different system elements (e.g., unsignalized intersections versus signalized intersections), but realizes that further research is needed to understand fully the variation in traveler perceptions of LOS across facility types.

LOS as Part of a Bigger Picture

No single performance measure tells the full story of roadway performance.

Neither LOS nor any other single performance measure tells the full story of roadway performance. Depending on the particulars of a given analysis, queue lengths, demand-to-capacity ratios, average travel speeds, indicators of safety, quantities of persons and vehicles served, and other performance measures may prove as or even more important to consider, whether or not they are specifically called out in an agency standard. For this reason, the HCM provides methods for estimating a variety of useful roadway operations performance measures, and not just methods for determining LOS. Chapter 7, Interpreting

AR0073925

HCM and Alternative Tool Results, lists the major performance measures available from each chapter of Volumes 2 and 3.

Duration of an operating condition can be important to know, since it helps describe the severity of the condition (e.g., the duration of a LOS F condition). In cases where demand exceeds capacity, duration must be known in order to set the analysis period long enough so that all demand is served and all relevant performance measures can be calculated properly. Frequency and probability of a particular condition occurring (e.g., likelihood or frequency of queue storage being exceeded during an analysis period) are also useful descriptors.

AR0073926

4. SERVICE MEASURES

DEFINITION AND CHARACTERISTICS

Service measures reflect traveler perceptions and can be influenced by agency actions.

Service measures are performance measures used to define LOS for transportation system elements.

Ideally, service measures should exhibit the following characteristics:

- Service measures should reflect travelers' perceptions (i.e., measures should reflect things travelers can perceive during their journey);
- Service measures should be useful to operating agencies (e.g., agency actions should be able to influence future LOS);
- Service measures should be directly measurable in the field (e.g., an analyst wishing to determine LOS for a two-lane highway used for recreational access can go to the field and directly measure average travel speed); and
- Service measures should be estimable given a set of known or forecast conditions (e.g., a method is provided in Chapter 15 to estimate the average travel speed for a two-lane highway, given inputs for roadway and traffic conditions).

SERVICE MEASURE SELECTION

Service measure selection.

Historically, the selection of a service measure or measures for an analysis methodology has been based on the collective opinion and judgment of TRB's HCQS Committee. The service measure threshold values that identify the breakpoints between each level of service have also been determined by the HCQS Committee. This approach was necessary, because until recently little information was available on the subject of how travelers evaluate operating conditions. However, it has been the intent of the committee to select service measures that it felt would be highly correlated with travelers' personal assessments of the operating conditions. Since 1993, there has been considerable more research focused on determining appropriate service measures based directly on traveler input. While this area of research was still immature at the time of publication of this edition of the HCM, the HCQS Committee intends to monitor and evaluate future research in this area for potential inclusion in subsequent editions of the HCM.

Studies that seek to determine service measures and thresholds based on traveler perceptions obviously use research approaches that directly involve a sample of travelers. Some of the methods used to obtain this direct traveler input include in-field experiments (e.g., driving or riding courses), simulated in-field experiments (such as through the use of video presentations), focus groups, and surveys. The study participants are typically asked to rate the conditions they are presented with on a scale of "very good" to "very poor," or something similar. The qualitative ratings are later converted to numeric values for analysis purposes. Some challenges to these types of studies include designing the instrument (field experiment, focus group, etc.) to capture all of the roadway, traffic, and control factors that might affect travelers' perceptions of operating

AR0073927

conditions; including factors that may not be relevant but could distract study subjects; recruiting an adequate sample of study participants from both a quantity and a diversity perspective; replicating desired conditions (for in-field experiments) for repeated observations; and accounting for the distribution of LOS responses that will result from each test scenario on the analysis methodology.

The advantage of this type of research approach is that, with application of an appropriate analysis methodology, multiple variables can be considered simultaneously, consistent with the high likelihood that travelers consider multiple factors when they evaluate the operating conditions. Including multiple factors also gives agencies more options in seeking to achieve a desired LOS for a given mode or in balancing the needs of various modes. All variables found to be statistically significant are incorporated into a mathematical function (more often referred to as a model). In the model, the coefficients (i.e., weighting factors) associated with each of the variables are determined directly through the statistical analysis. The output from such a model is a value often referred to as a LOS score. The LOS score value generally represents the average score that travelers would give a facility or service. Furthermore, some of the methodologies can directly estimate the threshold values that are used to distinguish between the LOS categories, again, on the basis of traveler input. To determine the LOS, the LOS score value is compared with the statistically estimated threshold values.

While variables representing any number of things can be included in this type of model, for models to be useful from a practical perspective, only variables representing operational or design conditions are usually included. Operational conditions refer to variables such as delay and speed (i.e., performance measures), while design conditions refer to variables such as median type and sidewalk presence. Traveler characteristics (e.g., age, gender, income) can certainly affect LOS perceptions; however, these data are difficult to collect in a transportation engineering situation. Thus, their study in a LOS model is limited.

Several methodological approaches have been applied to relate traveler perceptions directly to LOS, including regression-based methods (2–4), ordered probit models (5, 6), and fuzzy clustering (7). These studies have addressed facilities such as urban and rural freeways, arterial streets, and signalized intersections. LOS methods resulting from some of these studies have been included in the HCM 2010, while others have been studied by the HCQS Committee to improve the understanding of techniques used in estimating traveler-based LOS.

This edition of the HCM is the first to incorporate LOS methodologies that are based directly on results from traveler perceptions of LOS. As the field of traveler perception of LOS research continues to mature and results from regional studies are validated nationally, the HCQS Committee expects to continue to include these new LOS methodologies in future editions of the HCM. When research is not available to support traveler-perceived LOS methodologies,

AR0073928

HCQS Committee–selected service measures and thresholds continue to be used in this edition of the HCM.

DETERMINATION OF LOS F

The threshold between LOS E and LOS F is based on the judgment of the HCQS Committee in some instances and is determined directly from research on traveler perceptions of LOS in others. One example of where the service measure and LOS thresholds were determined by the HCQS Committee is basic freeway segments; density was selected as the service measure and the LOS E–F density threshold value was selected as the density at which traffic flow transitions from uncongested to congested. Bicycling on urban streets is an example of where the service measures were determined from traveler perception of LOS research; the LOS E–F threshold was chosen as a value that represents the transition to a totally unacceptable condition (i.e., an average rider will not ride under these conditions). Thresholds between LOS A and F may be based on ranges of values that define particular operating conditions or may simply provide an even gradation of values from LOS A to F. As mentioned previously, in some studies on traveler perceptions of LOS, the methodological approach explicitly yields the model variables (e.g., speed, median presence) as well as the specific LOS thresholds. However, these thresholds are still a function of the total number of LOS categories originally included in the study.

The volume-to-capacity (v/c) ratio (or, more correctly, the demand-to-capacity, d/c, ratio) is a special-case service measure. It cannot be directly measured in the field, nor is it a measure of traveler perceptions. Until capacity is reached (i.e., when flow breaks down on uninterrupted-flow facilities and when queues build on interrupted- or uninterrupted-flow facilities), the v/c ratio is not perceivable by travelers. Therefore, the HCM often uses the v/c ratio to define the LOS E–F threshold, but not to define other LOS thresholds.

The v/c ratio is often used to define the LOS E–F threshold, but not other LOS thresholds

SERVICE MEASURES FOR SPECIFIC SYSTEM ELEMENTS

Cross-Cutting Issues

Automobile Mode

A facility's capacity to serve the automobile mode reflects the effects of all motorized vehicles using the facility, including trucks, RVs, motorcycles, and intercity buses. In contrast, LOS for the automobile mode reflects the perspective of automobile drivers and passengers, but not necessarily the perspectives of other motorized vehicle users. Although automobiles are usually the dominant motorized vehicle type on roadways, analysts should use care in interpreting LOS results at special cases, such as intermodal-terminal access routes, where trucks may dominate.

LOS for the automobile mode is reflective of automobile driver and passenger perspectives, but not necessarily those of other motorized vehicle users

Pedestrian and Bicycle Modes

Depending on local regulations, pedestrians and bicycles may be allowed on all types of uninterrupted-flow facilities, including sections of freeways. However, research is only available to support LOS estimation methods for bicyclists traveling on two-lane and multilane highways. Pathways that are

AR0073929

Pathways parallel to freeways and multilane highways are analyzed by using the off-street facility procedures

parallel to freeways and multilane highways use the service measures for off-street pedestrian and bicycle facilities. Of the various types of interrupted-flow system elements, pedestrian and bicycle service measures are provided for urban street facilities, urban street segments, signalized intersections, and off-street pedestrian and bicycle facilities. Pedestrian LOS can also be calculated for two-way stop-controlled intersections and roundabouts.

Transit Mode

Bus service on uninterrupted-flow facilities typically serves longer distance trips, with few (if any) stops. The transit service measures provided in the *Transit Capacity and Quality of Service Manual* (TCQSM) (*8*) can be used to evaluate bus service along uninterrupted-flow facilities, as well as rail service operating within an uninterrupted-flow facility's right-of-way.

Transit service measures are provided only for urban streets. Consult the TCQSM for service measures for other situations.

The HCM provides transit service measures for urban street facilities and segments to facilitate multimodal comparisons of urban-street LOS. The TCQSM's service measures can be used to evaluate transit LOS at specific bus stops, for specific routes, for specific origin–destination pairs, and for specific areas. Some of the HCM's performance measures, such as delay, may also be useful in multimodal comparisons—for example, in comparing person-delay at an intersection with and without a transit preferential treatment, such as a queue jump lane.

Freeways and Multilane Highways

Automobile Mode

Density is the automobile service measure for all freeway and multilane highway system elements

Although travel speed is a major concern of drivers that relates to service quality, freedom to maneuver within the traffic stream and proximity to other vehicles are equally noticeable concerns. These qualities are related to the *density* of the traffic stream. Unlike speed, density increases as flow increases up to capacity, resulting in a service measure that is both perceivable by motorists and is sensitive to a broad range of flows. Density is used as the service measure for freeway facilities: basic freeway segments, ramp junctions, weaving segments, and multilane highways.

Bicycle Mode

Bicycle LOS for multilane highways is based on a bicycle LOS score model. The model uses variables determined from research that relate to bicyclists' comfort and perceived exposure while riding on multilane highways, such as separation from traffic, motorized traffic volumes and speeds, heavy-vehicle percentage, and pavement quality.

Higher vehicle volumes, a greater proportion of trucks and buses, and higher vehicle speeds all act to decrease a bicyclist's perceived comfort and traffic exposure. Striped bicycle lanes or roadway shoulders add to the perceived sense of traffic separation and improve the LOS. Pavement quality affects bicyclists' ride comfort: the better the pavement quality, the better the LOS.

AR0073930

Two-Lane-Highway Measures

Automobile Mode

Density expectations for and travel conditions on basic freeway and different from those for other uninterrupted-flow facilities.

Traffic operations on two-lane, two-way highways differ from those on other uninterrupted-flow facilities. Lane changing and passing are possible only in the face of oncoming traffic. Passing demand increases rapidly as traffic volumes increase, and passing capacity in the opposing lane declines as volumes increase. Therefore, on two-lane highways, unlike other types of uninterrupted flow facilities, normal traffic flow in one direction influences flow in the other direction. Motorists must adjust their travel speeds as volume increases and the ability to pass declines.

Efficient mobility is the principal function of major two-lane highways that connect major traffic generators or that serve as primary links in state and national highway networks. These routes tend to serve long-distance commercial and recreational travelers, and long sections may pass through rural areas without traffic control interruptions. Consistent high-speed operations and infrequent passing delays are desirable for these facilities.

Other paved, two-lane rural highways are intended to serve primarily an accessibility function. Although beneficial, high speed is not the principal concern. Delay—as indicated by the formation of platoons—is more relevant as a measure of service quality.

Two-lane roads also serve scenic and recreational areas in which the vista and environment are meant to be experienced and enjoyed without traffic interruption or delay. A safe roadway is desired, but high-speed operation is neither expected nor desired. For these reasons, three service measures are used for two-lane highways: *percent time spent following*, *average travel speed*, and *percent free-flow speed*.

Percent time spent following defined.

Percent time-spent-following represents the freedom to maneuver and the comfort and convenience of travel. It is the average percentage of travel time that vehicles must travel in platoons behind slower vehicles because of the inability to pass. Percent time spent following is difficult to measure in the field. However, the percentage of vehicles traveling with headways of less than 3 s at a representative location can be used as a surrogate measure.

Average travel speed defined.

Average travel speed reflects the mobility on a two-lane highway. It is the length of the highway segment divided by the average travel time of all vehicles traversing the segment in both directions during a designated interval.

Percent of free-flow speed defined.

Percent of free-flow speed represents the ability of vehicles to travel at or near the posted speed limit.

LOS criteria use one or two of these measures. On major two-lane highways, for which efficient mobility is paramount, both percent time-spent-following and average travel speed define LOS. However, roadway alignments with reduced design speeds will limit the LOS that can be achieved. On highways for which accessibility is paramount and mobility less critical, LOS is defined only in terms of percent time spent following, without consideration of average travel speed. On two-lane highways in developed rural areas, LOS is defined in terms of percent of free-flow speed.

AR0073931

Bicycle Mode

Bicycle LOS for two-lane highways is determined by a *bicycle* LOS score model in the same manner as described above for multilane highways, with the addition of on-highway parking as a factor that may exist on two-lane highways. The presence of on-highway parking negatively affects bicycle LOS because bicyclists tend to leave a buffer between themselves and parked vehicles, resulting in less separation between themselves and moving vehicles.

Urban Street Facility and Segment Measures

Automobile Mode

The service measure for the automobile mode on an urban street is the percent of base free-flow speed. Motorists traveling along arterial streets expect to be able to travel at or near the posted speed limit between intersections and to have to stop only infrequently. As delay due to traffic control devices and to other roadway users (e.g., vehicles stopped in a travel lane waiting to turn, buses stopping to serve passengers, or pedestrian crossings) increases, the lower the average speed and the lower the perceived LOS.

Research on automobile travelers' perceptions of LOS, as part of the National Cooperative Highway Research Program (NCHRP) 3-70 project, revealed that a combination of stops per mile and left-turn lane presence at signalized intersections had the highest statistical significance for predicting automobile LOS. However, the HCQS Committee elected to retain usage of a time-based service measure to analyze automobile LOS on urban streets for this edition of the HCM. The alternative NCHRP 3-70 methodology is also presented in Chapter 17, Urban Street Segments, since it is well suited for applications with a focus on determining multimodal LOS trade-offs and designing complete streets.

Urban street pedestrian LOS considers the quality of walking along a street, crossing at signalized intersections, and crossing the street between traffic signals.

Pedestrian Mode

Pedestrian LOS for urban streets is based on a *pedestrian* LOS score model that includes variables determined from research on pedestrians' perceptions of LOS. These variables relate to pedestrians' experiences walking along street segments between signalized intersections, crossing side streets at signalized intersections, and crossing the street between signalized intersections.

The segment component relates to both the density of pedestrians along the street and to pedestrian comfort and perceived exposure to traffic. The pedestrian-density indicator is a function of pedestrian volumes and sidewalk width, while the nondensity indicator is a function of separation from traffic due to distance and physical objects, sidewalk presence and width, and motorized traffic volumes and speeds. The worse of the two indicators is used to determine pedestrian-perceived segment LOS. The nondensity indicator is predominately used in suburban and rural settings.

The signalized-intersection component relates to pedestrian delay and perceived exposure to or interaction with traffic. The exposure elements of the calculation include potentially conflicting traffic volumes, parallel traffic volumes, parallel traffic speed, crossing width, and channelizing-island presence.

AR0073932

The roadway-crossing component is a function of the lesser of the delay in waiting for a gap to cross the street and the delay involved in diverting to the nearest signalized intersection. It also incorporates the segment and signalized-intersection components, which relate to the quality of the pedestrian environment experienced when pedestrians divert to a signal, either because of lower delay or a prohibition on crossings between signalized intersections.

Overall, pedestrian LOS is improved by the provision of sidewalks, wider sidewalks, a greater degree of separation from traffic, and reduced delays crossing the street at both signalized and unsignalized locations. Higher traffic volumes, higher traffic speeds, and wider streets all tend to reduce pedestrian LOS.

Bicycle Mode

Bicycle LOS for urban streets is based on a bicycle LOS score model that includes variables determined from research on bicycle riders' perceptions of LOS. These variables relate to bicyclists' experiences at signalized intersections and their experiences on street segments between signalized intersections. The intersection component relates to bicyclist comfort and perceived exposure to traffic and is a function of separation from traffic, cross-street width, and motorized traffic volumes. The segment component similarly relates to comfort and perceived exposure. It is a function of separation from traffic, motorized traffic volumes, traffic speeds, heavy vehicle percentage, presence of parking, and pavement quality. The frequency of unsignalized intersections and driveways between traffic signals is also a factor in the LOS score value.

Urban street bicycle LOS considers the quality of bicycling along the street between traffic signals and the quality of passage through signalized intersections.

Higher vehicle volumes, a greater proportion of trucks and buses, higher vehicle speeds, and presence of parking all act to decrease a bicyclist's perceived comfort and traffic exposure. Striped bicycle lanes or roadway shoulders add to the perceived sense of traffic separation and improve the LOS. Pavement quality affects bicyclists' ride comfort: the better the pavement quality, the better the LOS.

Transit Mode

Transit LOS for urban streets is based on a transit LOS score model that includes variables determined from research on transit riders' perceptions of LOS. These variables relate to passengers' experiences walking to a transit stop on the street, waiting for the transit vehicle, and riding on the transit vehicle. The walking to the stop component is based on the street's pedestrian LOS score. Transit passengers are usually pedestrians before and after their transit trip, and improvements to the pedestrian environment along streets with transit service contribute to a better LOS. The waiting component is a function of the transit vehicle frequency (relating to wait time and trip-making convenience), service reliability (unplanned passenger waiting time at the stop), and the presence of shelters and benches (which make waiting more comfortable). Finally, the riding-on-the-vehicle satisfaction is a function of average travel speed (a convenience factor) and passenger loads (a comfort factor).

The transit service measure applies to bus, streetcar, and at-grade light rail services that make stops along an urban street.

The service measure combines traveler perceptions relative to a transit stop, waiting for a transit vehicle, and riding on the vehicle.

AR0073933

Urban Street Intersections

Control delay is the automobile service measure for urban street intersections.

Automobile Mode

The service measure for the automobile mode at all urban-street intersections—including signalized intersections, all-way stop-controlled intersections, two-way stop-controlled intersections, roundabouts, and interchange ramp terminals—is *control delay*.

Control delay, which was defined in Chapter 4, Traffic Flow and Capacity Concepts, is a measure of driver discomfort, frustration, fuel consumption, and increased travel time. It depends on a number of variables, which are different depending on whether the intersection is signalized or unsignalized. As control delay increases, LOS worsens. The maximum control delay allowed for a given LOS at unsignalized intersections is lower than for signalized intersections due to differing driver expectations. In the HCQS Committee's opinion, the expectation of drivers is that a signalized intersection is designed to carry higher traffic volumes and experience greater delay than an unsignalized intersection.

Pedestrian, Bicycle, and Transit Modes

At the time of publication, there was insufficient research to be able to provide pedestrian and bicycle LOS for urban street intersections, except for signalized intersections and for pedestrians only—two-way stop-controlled intersections. The HCM provides transit LOS measures only at the urban street segment and facility levels.

Signalized Intersections

Pedestrian LOS at signalized intersections is based on a pedestrian LOS score model that incorporates conflicting motorized vehicle volumes and speeds, crosswalk length, average pedestrian delay, and the presence of right-turn channelizing islands. Pedestrian LOS improves with lower motorized vehicle volumes and speeds, shorter crosswalk lengths, lower delay, and the provision of right-turn channelizing islands.

Bicycle LOS at signalized intersections is based on a *bicycle LOS score* model that incorporates perceived separation from motorized vehicle traffic, motorized vehicle volumes, cross-street width, and presence and utilization of on-street parking. Bicycle LOS improves with greater perceived separation from motorized vehicle traffic, lower motorized vehicle volumes, shorter cross-street widths, and reduced on-street parking conflicts.

Two-Way Stop-Controlled Intersections

Pedestrian LOS at two-way stop-controlled intersections is based on average pedestrian *control delay* crossing the major street. Lower vehicle volumes, presence of a median, and provision of pedestrian crossing treatments that improve motorist yielding rates all help to improve pedestrian LOS.

AR0073934

Off-Street Pedestrian and Bicycle Facilities

Pedestrian Mode

The service measure for off-street exclusive pedestrian facilities is pedestrian space.

Off-street facilities used exclusively by pedestrians (e.g., pedestrian pathways, plazas, and concourses) use pedestrian space as the service measure. As the space available to pedestrians increases, the ability to move at one's desired speed along one's desired line of travel increases. Therefore, as the space available to a pedestrian on an off-street facility increases, so does the LOS.

The pedestrian service measure for shared off-street facilities is the number of times per hour a pedestrian avoids or is passed by bicycles.

When an off-street facility is shared by pedestrians and bicycles, pedestrian quality of service is much more affected by the bicyclists using the facility than by other pedestrians because of the speed differential between the two types of travelers. Therefore, the pedestrian service measure for shared off-street facilities is based on avoids—the number of times per hour that a pedestrian is met by or passed by bicyclists. The greater the number of bicyclists on a shared facility, the lower the pedestrian LOS.

Bicycle Mode

The bicycle service measure for all off-street facilities is a bicycle LOS score.

Bicycle LOS for off-street bicycle facilities, both exclusive and shared, is based on a bicycle LOS score model that includes variables determined from research on bicyclists' perceptions of LOS. These variables consist of the number of times a bicyclist passes other path users per minute, the number of times per minute on average that a bicyclist passes or is delayed in passing other path users, the presence of a centerline, and the path width. As the number of other path users (including bicyclists) increases, the LOS declines. Wider paths and the presence of a centerline contribute to better LOS.

It is well recognized that the models of the *Highway Capacity Manual* (HCM) are part of a continuum available to the analyst for highway capacity and quality-of-service analyses. For example, transportation planners and engineers have different needs in scope and level of detail. Planners focus on network performance in broad, general terms to understand supply–demand interactions between network capacity and flows. Of primary interest are the interactions of land uses and the transportation system. Engineers, in contrast, need to know how changes in the design of a specific system element or changes in the way it operates will affect its performance in terms of capacity, delays, queuing characteristics, and other measures. As a result, different traffic analysis tools are available to serve different analysis needs.

Chapter 6, HCM and Alternative Analysis Tools, begins by describing the HCM-based tools available to the analyst. In an *operations level analysis*, which is one such tool, HCM methodologies are applied directly and the user supplies all required inputs to the procedure. Many planning, preliminary engineering, and design applications do not require the level of accuracy provided by an operations analysis and substitute *default values* for some (or nearly all) of a methodology's inputs. *Generalized service volume tables* are sketch-planning tools that provide an estimate of the maximum volume a system element can carry at a given level of service (LOS), given a default set of assumptions about the system element. The use of local default values and local generalized service volume tables helps reduce the uncertainty in the results of analyses that use these tools, compared with using the HCM's national default values and tables. The chapter's two appendices provide guidance on developing local default values (Appendix A) and generating local generalized service volume tables (Appendix B).

Analysts might consider alternative tools as a supplement to HCM methods for a variety of reasons. Alternative tools might be considered in the following analyses, among others: those outside the range covered by an HCM methodology, those requiring performance measures not produced by the HCM, and those where the quantity of data required makes HCM methods impractical. To assist analysts in evaluating and applying alternative tools, this chapter describes traffic modeling concepts and terminology, identifies conceptual differences between analytical and simulation tools, provides a framework for applying alternative tools, and lists criteria to consider in the selection of a traffic analysis tool.

AR0073939

2. HCM-BASED TOOLS

GENERALIZED SERVICE VOLUME TABLES

Service volume tables provide estimates of the maximum number of vehicles a system element can carry at a particular LOS, given a set of assumed conditions.

A service volume table provides an analyst with an estimate of the maximum number of vehicles that a system element can carry at a given LOS. The use of a service volume table is most appropriate in certain planning applications in which evaluation of every segment or node within a study area is not feasible. Examples of these applications are city, county, or statewide planning studies where the size of the study area makes a capacity or LOS analysis for every system element infeasible. For these types of planning applications, the focus of the effort is to highlight potential problem areas (for example, locations where demand may exceed capacity or where a desired LOS threshold may be exceeded). For such applications, a service volume table can be a useful sketch planning tool, provided the analyst understands the limitations of this method. Once potential problem areas have been identified, other tools (HCM-based or alternative) can be used to perform more detailed analyses on locations of interest.

As described in more detail in Appendix 3, generalized service volume tables are developed by holding constant all input values to a particular HCM methodology—except demand volume. Demand volume is increased until the measure of effectiveness (MOE) for the methodology reaches the threshold for a given LOS (e.g., the threshold between LOS B and C). That demand volume then becomes the service volume for the given LOS (in the example above, for LOS B). The service volume represents the maximum number of vehicles that the system element can carry at the given LOS, given the assumed inputs.

Service volume results should be applied with care. Since actual conditions will have ways in some way from the assumptions used to develop the table.

The characteristics of any given system element will likely vary in some way from the assumed input values used to develop a service volume table. Therefore, the results from a service volume table should be treated as rough approximations. Service volume tables should not be used as a substitute for other tools when a final determination of the operational adequacy of a particular roadway is made.

The assumptions built into a table may be average (or typical) values or conservative values. The given affects how results from the table are interpreted.

For ease of use, generalized service volume tables require a minimum of user inputs—typically, key design parameters that have the greatest influence on a facility's capacity and LOS, such as the number of lanes. Given these inputs, a user can then read the service volume for a given LOS directly from the table and compare it with the actual or forecast volume for a system element. A volume greater than the service volume for the desired LOS indicates the need for further analysis. Depending on the assumptions used to develop the table (i.e., average or typical values versus conservative values) and the sensitivity of the service volumes to the default values used, volumes somewhat less than the identified service volume (as much as 25% below the service volume in some cases) could also suggest the need for further analysis.

Service volumes can be sensitive to the choice of input values, depending on the particular methodology and input parameters.

AR0073940

APPLICATION OF DEFAULT VALUES TO HCM METHODOLOGIES

Many planning, preliminary engineering, and design analyses apply HCM methodologies directly but use default values for some to many of the input parameters.

In most planning, preliminary engineering, and design applications of the HCM, an analyst applies an HCM methodology taken directly from one or more of the chapters in Volumes 2 and 3 but uses default values for some (or many) of the input parameters. These types of analyses are frequently used to evaluate or design for future operations. Therefore, not all of the input parameters required by an HCM methodology (e.g., heavy-vehicle percentage or peak hour factor) may be available or readily forecast. Default values can also be applied when current operations are evaluated as part of a screening effort, similar to the way service volume tables are applied. Because users have control over which input parameters are defaulted, the uncertainty of the analysis results is reduced compared with the application of a service volume table, which potentially reduces the number of problem areas flagged for further analysis.

Although the HCM provides default values for a number of methodologies, the analyst should be mindful that these values represent typical national values and that typical conditions within a state, region, or community may be different. When default values occur frequently in analyses, the use of local default values can help further reduce the uncertainty in the analysis results. Appendix A provides guidance on developing local default values.

OPERATIONS-LEVEL HCM ANALYSIS

Operations-level HCM analyses apply the HCM methodology directly and use no or minimal default values.

In an operations-level analysis, an analyst applies an HCM methodology directly from one or more of the chapters in Volumes 2 and 3 and supplies a full set of required input parameters from measured or forecast values. No or minimal default values are used. Therefore, compared with the generalized service volume tables and the application of default values, operations-level analyses provide the highest level of accuracy. However, as discussed in Chapter 7, Interpreting HCM and Alternative Tool Results, analysts must still account for variability, uncertainty, and measurement errors in input data, and their impact on the analysis outputs, in the interpretation of analysis results.

The chapters in Volumes 2 and 3 identify methodological limitations and special cases where analysts may wish to consider alternative tools.

An operations-level analysis is applicable to any situation covered by an HCM methodology. Analysts should refer to the Limitations of the Methodology and Special Cases sections of the HCM chapter that covers the system element being evaluated to ensure that the HCM methodology is appropriate for the specifics of the situation being studied. A situation that is outside the range of conditions covered by the methodology would be one reason for considering an alternative tool. Other cases when alternative tools might be considered are discussed in the next section.

AR0073941

3. ALTERNATIVE TOOLS

OVERVIEW

Alternative tools include all non-HCM procedures that may be used to evaluate highway system performance.

Alternative tools include all analysis procedures outside of the HCM that may be used to compute measures of transportation system performance for analysis and decision support. Most alternative tools take the form of software products, and there is an abundance of literature describing alternative tools and their applications. The purpose of this section is to categorize the most commonly used tools, to identify the conditions under which they might be used to supplement the HCM procedures, and to suggest a framework and guidelines for their application that will maximize their compatibility with the HCM deterministic procedures. The intent is not to identify or compare specific tools or to duplicate the wealth of literature that exists on the general subject of traffic performance analysis.

This section describes the types of available tools (which are generally software products) but does not identify or compare specific tools.

Clearly, readers should use the material presented here in conjunction with other documents that also address analysis, modeling, and simulation of transportation systems. A considerable volume of authoritative information on this subject is available in the Federal Highway Administration's *Traffic Analysis Toolbox*. Four volumes of the *Toolbox* provide general guidance on the use of traffic analysis tools, including the HCM.

A useful reference on traffic operations modeling is the Federal Highway Administration's Traffic Analysis Toolbox.

- *Volume I: Traffic Analysis Tools Primer* (1) presents a high-level overview of the different types of traffic analysis tools and their role in transportation analyses.
- *Volume II: Decision Support Methodology for Selecting Traffic Analysis Tools* (2) identifies key criteria and circumstances to consider in selecting the most appropriate type of traffic analysis tool for the analysis at hand.
- *Volume III: Guidelines for Applying Traffic Microsimulation Modeling Software* (3) provides a recommended process for using traffic microsimulation software in traffic analyses.
- *Volume IV: Definition, Interpretation, and Calculation of Traffic Analysis Tools Measures of Effectiveness* (4) describes the appropriate definition, interpretation, and computation of MOEs for traffic operations and capacity improvements. This report provides information and guidance on which MOEs should be produced, how they should be interpreted, and how they are defined and calculated in traffic analysis tools. The document recommends a basic set of MOEs that can help rapidly assess the current problems and the benefits of alternative improvements at the system level, in a form readily understandable by the decision maker.

Other volumes of the *Toolbox* deal with the application of alternative tools for specific application scenarios.

The material in this section focuses primarily on the automobile mode. The importance of other modes - particularly bicycles, pedestrians, and transit—is recognized, however, experience with the use of alternative tools to address these modes is limited. Some alternative tools address nonautomobile modes

AR0073942

explicitly and some do not. The *Traffic Analysis Toolbox* (*1–3*) mentions the inability to deal with "interferences that can occur between bicycles, pedestrians, and vehicles sharing the same roadway" as a limitation of most simulation tools. Where appropriate, specific guidance is presented on the treatment of bicycles, pedestrians, and buses in the chapters of Volumes 2 and 3. The best source of guidance for the use of alternative tools for other modes is the detailed documentation and user's guide provided with tools that offer these features.

TRAFFIC MODELING CONCEPTS AND TERMINOLOGY

Hierarchy of Modeling Terminology

Modeling terminology has not been applied consistently throughout the realm of traffic analysis tools. For purposes of the HCM, the following terminology will be used to distinguish between different objects and processes that have been referred to in the literature simply as a "model."

- An *algorithm* is, by dictionary definition (*4*), "a set of rules for solving a problem in a finite number of steps." This definition suits the HCM's purposes.
- A *model* is, by dictionary definition (*5*), "a hypothetical description of a complex entity or process." Here is the root of the inconsistent usage. By this definition the word can be, and has been, applied to many different objects. A more focused definition is required. One definition in common use is that a model is "a representation of a system that allows for investigation of the properties of the system and, in some cases, prediction of future outcomes" (*6*). For HCM purposes, the term will be used in this sense but will be more precisely defined as "a procedure that uses one or more algorithms to produce a set of numerical outputs describing the operation of a highway segment or system, given a set of numerical inputs." By this definition, each of the performance analysis procedures specified in Volumes 2 and 3 constitutes a model. This term will generally be used with an adjective to denote its purpose (e.g., *delay model*).
- A *computational engine* is the software implementation of one or more models that produces specific outputs given a set of input data.
- A *traffic analysis tool*, often abbreviated in the HCM as a "tool," is a software product that includes, at a minimum, a computational engine and a user interface. The purpose of the user interface is to facilitate the process of entering the input data and interpreting the results.
- A *model application*, sometimes referred to as a *scenario*, specifies the physical configuration and operational conditions to which a traffic analysis tool is applied.

Inconsistency in terminology arises because each of these five objects has been characterized as a model in the literature, since each one satisfies the dictionary definition. The distinction between the five terms is made here in the hope of promoting more consistent usage.

AR0073943

Additional Modeling Definitions

Another set of terminology that requires more precise definitions deals with the process by which the analyst ensures that the modeling results provide a realistic representation of the real world. The following terms are defined elsewhere (3):

- *Verification*. The process by which the software developer and other researchers check the accuracy of the software implementation of traffic operations theory. The extent to which a given tool has been verified is listed as an important tool selection criterion in this chapter.
- *Calibration*: The process by which the analyst selects the model parameters that cause the model to best reproduce field-measured local traffic conditions.
- *Validation*: The process by which the analyst checks the overall model-predicted traffic performance for a street–road system against field measurements of traffic performance, such as traffic volumes, travel times, average speeds, and average delays. Model validation is performed on the basis of field data not used in the calibration process.

Traffic Analysis Tool and Model Categories

The *Traffic Analysis Toolbox* identifies the following categories of traffic analysis models:

- *Sketch-planning tools* produce general order-of-magnitude estimates of travel demand and transportation system performance under different transportation system improvement alternatives.
- *Travel demand models* forecast long-term future travel demand on the basis of current conditions and projections of socioeconomic characteristics and changes in transportation system design.
- *HCM-based analytical deterministic tools* quickly predict capacity, density, speed, delay, and queuing on a variety of transportation facilities.
- *Traffic signal optimization tools* are primarily designed to develop optimal signal phasing and timing plans for isolated signalized intersections, arterial streets, or signal networks.
- *Macroscopic simulation models* are based on the deterministic relationships of the flow, speed, and density of the traffic stream.
- *Microscopic simulation models* simulate the movement of individual vehicles on the basis of car following and lane changing theories.
- *Mesoscopic models* combine the properties of microscopic and macroscopic simulation models.
- *Hybrid models* employ macroscopic and mesoscopic models simultaneously. These tools are intended to be applied to very large networks containing critical subnetworks connected by several miles of essentially local facilities. Microscopic modeling is applied to the critical subnetworks, while the connecting facilities are modeled at the

Hybrid models, used with very large networks, apply macroscopic modeling to critical subnetworks and mesoscopic or macroscopic modeling to the connecting facilities.

AR0073944

meso-analytic or macroscopic level. Regional evaluation models are a typical example of hybrid model application.

Stochastic and Deterministic Models

A *deterministic* model is not subject to randomness. Each model run will produce the same outcome. If these statements are not true and some attribute of the model is not known with certainty, the model is *stochastic*. Random variables will be used to represent those attributes of the model not known with certainty. Descriptions of how these random numbers are selected to obtain sample values of the parameter of interest (i.e., from its cumulative distribution function) can be found in various texts (e.g., 7–10). Different random number sequences will produce different model results; therefore, the outcome from a simulation tool based on a stochastic model cannot be predicted with certainty before analysis begins. Stochastic models and the user in interpreting variability and uncertainty into the analysis.

The HCM's methodologies are deterministic: given the same set of inputs, the methods will produce the same result each time.

Most simulation models are stochastic: given identical inputs but a different random number seed, model runs will produce different results.

Static Flow and Time-Varying Flow Models

The terms *static flow* and *time-varying flow* relate to the temporal characteristics of the traffic flows in the simulation model. Basically, the terms differentiate between a model that uses constant traffic flow rates from one time period to another and a model that does not. This differentiation is not to be confused with whether the model can represent internally time-varying flows that occur because of simulated events (e.g., incidents, signal cycling, ramp metering, high occupancy vehicle lane closures). The difference is in the type of input flows that can be specified.

In static flow models, users provide a single set of flow rates. The model may vary headways, but the O-D matrix is fixed and does not change throughout the duration of the analysis.

Time-varying models allow flow rates to change with time. Users supply more than one set of flow rates so that the O-D matrix can vary over time. Most models change flows once an hour, but some allow more frequent changes.

In the static flow case, traffic flows are provided just once as a set of constants. A tool may vary the individual headways stochastically, but the flow rates are fixed. Put another way, the origin-destination (O-D) matrix is fixed and does not change throughout the duration of the analysis.

In the time-varying case, flow rates can change with time. More than one set of flow rates must be specified so that the O-D matrix can vary over time. The flexibility of specifying more than one set of flow rates is particularly useful when major surges in traffic need to be examined, such as the unloading of a special event or peak periods when a pronounced variation in traffic flows exists.

Descriptive and Normative Models

The terms *descriptive* and *normative* refer to the objective of performing the analysis with a simulation models. If the objective of the model is to describe how traffic will behave in a given situation, the model is most likely to be descriptive. It will not try to identify a preferred set of parameters that provide the best system performance but rather will show how events will unfold given a logic that describes how the objects involved will behave. For example, a simulation model could predict how drivers will behave in response to traffic flow conditions. A model attempting to shape that behavior by trying to force drivers to maintain specific headways would not be a descriptive model.

Descriptive models show how events unfold given a logic that describes how the objects involved will behave.

Normative models try to identify a set of parameters that provide the best system performance.

Normative models try to identify a set of parameters that provide the best system performance. An external influence (most often referred to as an objective

AR0073945

functionality to force the system to behave in some optimal way. A good example is a model that tries to optimize signal timings. Another illustration is a freeway network model that requires drivers to alter their path choices to optimize some measure of system performance. In both cases, the behavior of the system is modified through an external influence, probably on an iterative basis, to create a sequence of realizations in which the objective function value is improved, as in minimizing total travel time or total system delay.

The distinction can be restated this way: if the model has an objective and seeks to optimize that objective, it is a normative model. Conversely, if it has an objective but does not seek to optimize that objective by changing the design or operational parameters (e.g., signal timing), it is a descriptive model.

Traffic assignment models are a special case, because they are based on an objective that is gradually improved over a sequence of iterations. In this case, the objective is for each driver to minimize either the travel time for the trip or some other quantitative measure of the general cost or disutility associated with the trip. Traffic assignment models are characterized as either static or dynamic, depending on whether the O-D characteristics are constant or time-varying. Most simulation tools have some form of dynamic traffic assignment (DTA). Because of its demands on computer resources, DTA is often implemented at the mesoscopic level. DTA models are often embedded in traffic microsimulation tools.

DTA models are a special case of descriptive models that are based on an objective (minimize the travel time or disutility associated with a trip) that is gradually improved over a sequence of iterations until the network reaches a state of equilibrium.

The optimization process may be characterized as either *system-optimal* or *user-optimal*. A user-optimal solution does not necessarily produce an optimal result for the system as a whole and vice versa. With user-optimal models, the objective being applied reflects a behavioral assumption, and therefore the model is primarily descriptive. System-optimal models enforce some changes in driver behavior and are therefore normative. The formulation of the generalized cost (disutility) function can be expanded to reflect actual driving behavior more accurately—for example, by taking into account the number of stops or the driver's familiarity with typical traffic conditions.

The important point is that the analyst needs to know which type of model is being used and how that type influences the model's predictions. For example, assume that the analyst is dealing with a scenario in which the signal timings are fixed and drivers can alter their path choices in response to those signal timings (in a way that replicates how they would actually behave). This is a descriptive model, and is a common application of a DTA model as mentioned above. Even though the analyst can change the signal timings and see how the drivers respond (and how the system performance changes), the model is still describing how the system would behave for a given set of conditions. On the other hand, if the analyst alters the scenario so that it seeks a better set of signal timings, a normative model has been created.

A descriptive model is implied if the analyst introduces a new demand–supply paradigm, such as congestion pricing, based on a field study. A new demand-side routine could be developed to predict how drivers alter path choices in response to congestion prices, and a supply-side routine could be developed that seeks to set those prices in some responsive and responsible way.

AR0073946

in an effort to produce a desirable flow pattern. Even though two competing optimization schemes are at work, each describes how a portion of the system is behaving in response to inputs received. There is an explicit intent to optimize the system performance in a specific manner.

CONCEPTUAL DIFFERENCES BETWEEN DETERMINISTIC AND SIMULATION TOOLS

There are some conceptual differences between the HCM's analytical modeling and simulation modeling. It is useful to examine these differences before addressing alternative tool applications. Most of the differences may be described in terms of the way analytical and simulation tools deal with various traffic flow phenomena. Examples of the significant differences are identified in general terms in Exhibit 6-1.

APPROPRIATE USE OF ALTERNATIVE TOOLS

Situations where alternative tools might supplement HCM procedures.

Using alternative tools to supplement HCM capacity and quality-of-service procedures should be considered when one or more of these conditions apply:

- The configuration of the facility has elements that are beyond the scope of the HCM procedures. Each procedural chapter identifies the specific limitations of its own methodology.
- Viable alternatives being considered in the study require the application of an alternative tool to make a more informed decision.
- The measures produced by alternative tools are compatible with corresponding HCM measures and are arguably more credible than the HCM measures.
- The measures are compatible with corresponding HCM measures and are a by-product of another task, such as optimization of a network traffic control system.
- The measures are compatible with corresponding HCM measures and the decision process requires additional performance measures, such as fuel consumption and emissions, which are beyond the scope of the HCM.
- The system under study involves a group of different facilities on travel routes with mutual interactions invoking several procedural chapters of the HCM. Alternative tools are able to analyze these facilities as a single system.
- Routing is an essential part of the problem being addressed.
- The quantity of input or output data required presents an intractable problem for the HCM procedures.
- The HCM procedures predict oversaturated conditions that last throughout a substantial part of a peak period or queues that overflow the available storage space, or both.

AR0073947

Exhibit 6–1
Comparison of Methods for Addressing Traffic Phenomena by the HCM and Typical Microsimulation Tools

Traffic Phenomenon	Deterministic (HCM) Treatment	Typical Microsimulation Treatment
Right-turn on red	Subtract right-turn-on-red volume from demand	Microscopic model of gap acceptance and follow-up time
Permitted left turns	Empirical model of capacity versus opposing volume, with minimum capacity determined by an assumption of two sneakers per cycle	Microscopic model of gap acceptance and follow-up time
STOP sign entry	Macroscopic model of gap acceptance and follow-up time	Microscopic model of gap acceptance and follow-up time
Channelized right turns	Subtract right-turning volume from demand	Microscopic model of gap acceptance and follow-up time, implicit effects of right-turn queues
Ramp merging	Empirical model of merge capacity versus freeway volume in the two outside lanes	Microscopic model of gap acceptance and follow-up time (some tools incorporate cooperative merging features)
Merging during congested conditions	Not addressed	Microscopic model of gap acceptance
Lane-changing behavior	Macroscopic model based on demand volumes and geometrics	Microscopic model of lane changing behavior
Queue start-up or green	Fixed start-up lost time subtracted from the displayed green time	Stochastic lost time applied to the first few vehicles in the departing queue
Response to change interval	Fixed extension of green time added to the displayed green time	Kinematic model of stopping probability
Actuated signal operation	Deterministic model for computing green times as a function of demand and operating parameters	Embedded logic emulates pretimed/actuated control logic, tools vary in the level of emulation detail
Delay accumulation	Analytical formulation for uniform delay based on the assumption of uniform arrivals over the cycle and uniform departures over the effective green	These three effects are combined implicitly in the accumulation and discharge of individual vehicles over the analysis period
Progression quality	Adjustment factor applied to the uniform delay term	
Random arrivals	Analytical formulation for incremental delay	
Generation of vehicles	Incremental delay formulation assumes Poisson arrivals (mean = variance) at the stop line; the variance-to-mean ratio is reduced for traffic-actuated control as a function of the unit extension	Individual vehicles are introduced into entry links randomly, on the basis of a specified distribution
Effect of oversaturation	A third analytical formulation, d_3, is introduced to cover the additional delay due to an initial queue	Oversaturated operation and residual queues are accounted for implicitly in the accumulation and discharge of individual vehicles
Residual queue at the end of analysis period	Analytical formulation computes the residual queue when $d/C > 1.0$; the residual queue from one period becomes the initial queue for the next period	

AR0073948

In addition, when a specific HCM procedure has been developed by using simulation results as a surrogate for field data collection, it might be appropriate to use the underlying simulation tool directly to deal with complex configurations that are not covered in the HCM.

The following are factors to consider in the decision to use an alternative tool:

- Is the use of the alternative tool acceptable to the agency responsible for approving the decisions that result from its use?
- Are the necessary resources, time, and expertise available to apply the alternative tool?
- Does the application rely on a traceable and reproducible methodology?
- Have assumptions used to apply the tool been sufficiently documented?
- Is sufficient time available for calibration to promote a robust reliance on the model output?
- Are sufficient and appropriate data available to capitalize on or leverage the strength of the alternative tool?
- Are the alternative tool's performance measures (output) defined and computed in a manner consistent with the specifications given in Chapter 7, Interpreting HCM and Alternative Tool Results?

Exhibit 6-2 provides examples of typical alternative tool applications for various situations that occur with both interrupted and uninterrupted flow conditions. Corridor and areawide analyses are also addressed. In this exhibit HCM procedures, which focus on points on the roadway and on linear roadway systems, tend to have limitations that are best addressed by tools that explicitly model corridors and areawide transportation systems.

For corridor and areawide analysis, aggregation of the results from Volume 2 and Volume 3 procedures requires an intractable amount of data and effort. The interaction between individual facilities cannot be accounted for by HCM procedures. DTA might be required to balance flows among facilities and to model congestion propagation through the network due to oversaturation. Examples of promising alternative tool applications include active traffic management (ATM), congestion pricing, and freight corridors.

Alternative tool applications may be most appropriate for the evaluation of ATM measures that address operating conditions not explicitly addressed by HCM procedures. ATM consists of the dynamic and continuous monitoring and control of traffic operations on a facility. Examples of ATM measures include congestion pricing, managed lanes, ramp metering, changeable message signs, incident response, and speed harmonization (variable speed limits).

More information on ATM strategies and their evaluation can be found in Chapter 35, Active Traffic Management.

ATM measures, because of their dynamic nature, cannot be adequately modeled with HCM procedures. HCM procedures assume steady-state demand and control conditions within the typical minimum 15 min analysis period. Alternative tool applications that model traffic operations and interactions with traffic controls at the minute-by-minute level will be more accurate than HCM procedures that model operations at the higher level of temporal aggregation.

Exhibit 6-2
Typical Applications for Alternative Traffic Analysis Tools

HCM Chapter	Typical Alternative Tool Application
Typical Applications in Volume 2: Uninterrupted Flow	
Applicable to all uninterrupted flow procedures	Bottlenecks Oversaturated flow analysis Time-varying demands Unbalanced lane use Special lane restrictions Surveillance, work zones
10. Freeway Facilities	Managed lanes Surface street traffic control and ramp metering
11. Basic Freeway Segments	See uninterrupted-flow situations above
12. Freeway Weaving Segments	Complex weaving areas
13. Freeway Merge and Diverge Segments	Ramp metering High-occupancy vehicle ramp lanes
14. Multilane Highways	See uninterrupted flow situations above
15. Two-Lane Highways	Combination of terrain and traffic characteristics such as presence of passing lanes or coefficient of variation of desired speeds
Typical Applications in Volume 3: Interrupted Flow	
Applicable to all interrupted-flow procedures	Oversaturated flow analysis (except for signalized intersections) Bus activity On-street parking Special lane use Queue spillback Pedestrian–bicycle interactions
16. Urban Street Facilities	Multimodal system analysis
17. Urban Street Segments	Mix of signals and no signals (stop and yield) Effects of midblock bottlenecks Signal timing plan development Turn bay overflow
18. Signalized Intersections	Geometrically offset intersections Alternative arrival characteristics Phase skips Pedestrian actuation Timing plan development
19. Two-Way STOP-Controlled Intersections	Two-way left turns Yield-controlled intersection delay TWSC intersection on a signalized arterial
20. All-Way Stop-Controlled Intersections	AWSC intersection on a signalized arterial
21. Roundabouts	Roundabout on a signalized arterial Multilane roundabouts Effect of geometrics Mixed-mode traffic
22. Interchange Ramp Terminals	Full cloverleaf interchange Back up from freeway segments Long-term (i.e., multicycle) blockage of approaches
23. Off-Street Pedestrian and Bicycle Facilities	Limit of modeling of pedestrian crossing activity

AR0073950

APPLICATION FRAMEWORK FOR ALTERNATIVE TOOLS

A wide range of tools is available for application to most highway capacity and performance analysis situations. Each tool has certain inputs and outputs, some of which can support a productive flow of information between tools. This section discusses the classes of tools that are available to address different types of system elements and suggests a framework for their application. Since the application framework differs among system elements, each element will be discussed separately. In developing input data for all these elements, it is important to reflect local default values.

Freeways

The modeling framework for freeways is presented in Exhibit 6-3. Each of the tools and procedures can be used in a stand-alone fashion; the potential flow of information between them indicates how they might fit into an overall analysis structure.

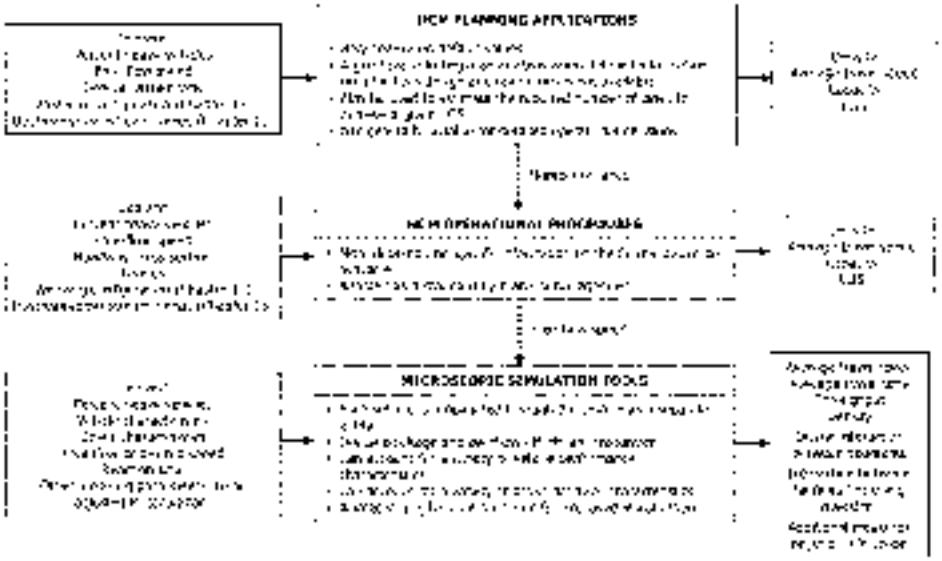

Exhibit 6-3
Freeway Modeling Framework for the HCM and Alternative Tools

The principal classes of tools are

- The HCM planning applications, which rely heavily on default values for parameters;
- The HCM operational applications that require more detailed inputs in place of the default parameter values; and
- Microscopic simulation tools, as described previously in this chapter.

Tools available for modeling freeways include HCM planning procedures, HCM operational procedures, and microscopic simulation.

Alternative tools find a much stronger application to freeway facilities than to individual freeway segments.

Most HCM freeway analysis limitations are apparent when the freeway is analyzed as a facility consisting of multiple segments or different types (basic segments, ramps, weaving segments, etc.) by using the procedures given in Chapter 10, Freeway Facilities. Alternative tools, especially microsimulation tools, find a much stronger application to freeway facilities than to individual segments.

AR0073951

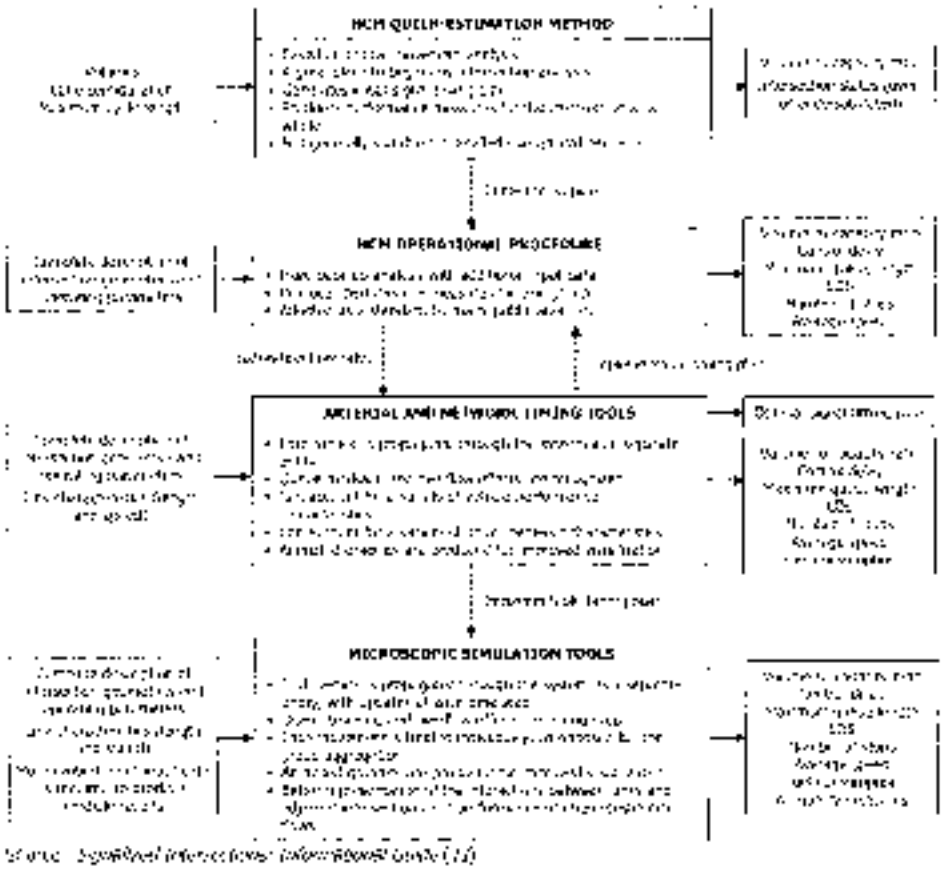
Urban Streets

Tools available for modeling urban streets include the HCM quick-estimation method for signalized intersections, HCM operational methods, arterial and network signal-timing tools, and microscopic simulation.

The modeling framework for urban streets, including their intersections, is presented in Exhibit 6-4. Each of the tools and procedures can be used in a stand-alone fashion; the potential flow of information between them indicates how they might fit into an overall analysis structure. The principal classes of tools are

- The HCM quick-estimation method for signalized intersections, which is based primarily on critical movement analysis and default values;
- The HCM operational methods for urban streets, including all types of intersections, which require more detailed traffic inputs and operating parameters;
- Arterial and network signal-timing tools, which produce recommended signal-timing plans based on measures that are generally similar to those produced by the HCM procedures; and
- Microscopic simulation tools, as described previously in this chapter.

Exhibit 6-4
Urban Street Modeling Frameworks for the HCM and Alternative Tools



Source: *Signalized Intersections: Informational Guide* (1)

Signal-timing tools generate signal-timing plans that can be used as inputs to HCM operational methods or to microsimulation tools.

Signal-timing tools are mostly based on macroscopic analytical models of traffic flow. Because they are the only class of urban street analysis tool that generates a signal timing plan as output, they are frequently used as an alternative tool for this purpose. The signal timing plan may be fed into the HCM operational analysis or used as input to a microsimulation tool.

AR0073952

Microsimulation tools are used in urban street analysis, mainly to deal with complex intersection phenomena beyond the limitations of the HCM. These tools evaluate interactions between arterial segments, including the effect of various types of unsignalized intersections. They are also applied in evaluating networks and corridors with parallel facilities with the use of DTA routines.

Microsimulation tools are used to deal with complex intersection interactions beyond the limitations of the HCM.

Two-Lane and Multilane Highways

At this point, there is minimal application of alternative tools for the analysis of either type of highway. The HCM is the only macroscopic deterministic tool in common use, although some states such as Florida have developed their own analysis tools that implement derivatives of HCM procedures (12). At the time of writing, microsimulation models were in various stages of development. Some two-lane highway simulation tools were beginning to emerge, but there was insufficient experience to provide guidance for their use as an alternative to the methodology provided here.

At the time of writing, the HCM was the only deterministic tool in common use for two-lane and multilane highways.

Corridor and Areawide Analysis

Corridor and areawide analysis is an important application for alternative tools. The HCM procedures deal mainly with points and segments and are limited in their ability to recognize the interaction between segments and facilities. The overall modeling framework for corridor and areawide analysis is presented in Exhibit 6-5, which shows the relationship of the HCM to the broad field of corridor and areawide analysis models.

Corridor and areawide analysis is probably the most important application for alternative tools.

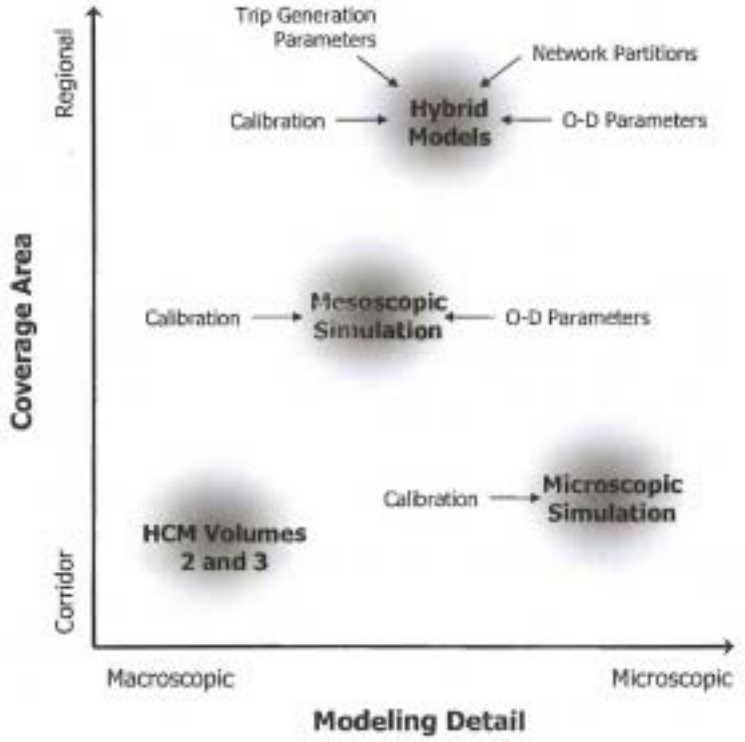


Exhibit 6-5
Corridor and Areawide Analysis Modeling Framework for the HCM and Alternative Tools

AR0073953

An excellent reference for corridor and areawide simulation (13) is emerging from a U.S. Department of Transportation research initiative on integrated corridor modeling, providing detailed guidance on the conduct of large-scale simulation projects. This section presents an overview of corridor and areawide simulation from the perspective of HCM users, but considerably more detailed information is presented in the report (13), including a more detailed analysis framework.

The framework for corridor and areawide analysis differs from the framework presented for freeways and urban streets in three ways:

1. The HCM procedures account for a much smaller part of the modeling framework.
2. Different levels of simulation modeling are represented here. Simulation of urban streets and freeways is typically performed only at the microscopic level.
3. The framework is two-dimensional, with the coverage area as one dimension and the modeling detail as the other.

The selection of a model class (microscopic, mesoscopic, or hybrid) reflects a trade-off between coverage area and modeling detail.

The various model classes shown in Exhibit 6-5 depict the trade-off between these characteristics. The trade-off between coverage area and modeling detail is evident:

- Microscopic simulation provides more detail and more coverage than the HCM procedures. The additional detail comes from the microscopic nature of the model structure. The additional coverage comes from the ability to accommodate multiple links and nodes.
- Mesoscopic simulation provides more coverage with less modeling detail than microscopic simulation. In addition to accommodating larger areas, mesoscopic models are computationally faster than microscopic models and are thus well suited to the iterative simulations required for DTA, which can be time-consuming.
- Hybrid modeling uses network partitioning to treat more critical parts of the system microscopically and less critical parts mesoscopically—or even macroscopically. In this way, the regional coverage may be expanded without losing essential detail. A typical application for hybrid modeling might be interurban evacuation analysis, which must accommodate a very large geographical area without loss of detail at critical intersections and interchanges.

Some examples of corridor modeling are presented in Volume 4 of the HCM.

PERFORMANCE MEASURES FROM ALTERNATIVE TOOLS

The tool selected for a given analysis needs to provide performance measures that realistically reflect the attributes of the problem being studied.

Before the analyst can select the appropriate tool, the performance measures that realistically reflect attributes of the problem under study must be identified. For example, when oversaturated conditions are studied, it is necessary to use a tool that quantifies the effects of queuing as well as stops and delay. If the methodologies presented in Volumes 2 and 3 do not provide a particular performance measure of interest to the analyst (e.g., fuel consumption and emissions), an alternative tool might be required. Exhibit 6-6 provides a

AR0073954

summary of important performance measures for the procedures discussed in Volumes 2 and 3. The applicability of the HCM procedures and alternative tools is indicated for each chapter in this exhibit.

- A: Performance measure computed by alternative tools (mostly simulation-based).
- X: Performance measures do not apply to this chapter.

TWSC: Two-way stop-controlled. AWSC: All-way stop-controlled.

Source: Adapted from Dowling et al. [5].

When an alternative tool is used to analyze highway capacity and quality of service, its performance measures should ideally be compatible with those prescribed by the HCM. Chapter 7 provides general guidance on this topic, while selected chapters in Volumes 2 and 3 provide specific guidance for certain system elements.

If an alternative tool is used to analyze highway capacity and quality of service, then the performance measures generated by the tool should, to the extent possible, be compatible with those prescribed by the HCM. Alternative tools frequently apply the same terminology to performance measures as the HCM, but divergent results are often obtained from different tools because of differences in definitions and computational methods. General guidance on reconciling performance measures is given in Chapter 7, Interpreting HCM and Alternative Tool Results. More specific guidance on dealing with performance measures from alternative tools is given in several of the procedural chapters in Volumes 2 and 3.

TRAFFIC ANALYSIS TOOL SELECTION CRITERIA

The success of a traffic analysis project depends on the selection of the best tool or tools for the purpose, followed by the proper application of the selected tools. Both of these issues are addressed in detail in the *Traffic Analysis Toolbox*, and the guidance provided in the *Toolbox* should be studied thoroughly before a major traffic analysis project is undertaken.

Determining Project Scope

Questions to ask during the scoping of a traffic analysis project.

A properly defined problem and project scope are essential prerequisites to the correct selection of tools or procedures for the project. Answers to the following questions will assist in scoping the project:

AR0073955

1. What is the operational performance problem or goal of the study?
2. Does the network being studied include urban streets, freeways, rural highways, or any combination of them?
3. Are multiple routes available to drivers?
4. What are the size and topology (isolated junctions, linear arterial, grid) of the network?
5. What types of roadway users (cars, carpools, public transit vehicles, trucks, bicycles, pedestrians) should be considered?
6. What traffic control methods (regulatory signs, pretimed signals, actuated signals, real-time traffic-adaptive signals, and ramp metering signals) should be considered?
7. Should oversaturated traffic conditions be considered?
8. Does the network involve specialized traffic control or intelligent transportation system (ITS) features that are not covered by the HCM?
9. What is the duration of the analysis period?
10. Do the geometric conditions of the roadway facility change during the analysis period?
11. Does the traffic demand fluctuate significantly during the analysis period?
12. Does the traffic control change during the analysis period?
13. What output and level of detail are anticipated from the tool?
14. What information is available for model input, model calibration, and validation?
15. Are multiple methods available for consideration in the analysis?

Assessing HCM Methodologies

Use the Limitations of the Methodology and Special Cases sections of volume 2 and 3 chapters to assess the appropriateness of the HCM methodology for a given analysis

Another essential step in the analysis tool selection process is to assess the capability of the existing HCM methodologies and to determine whether these methodologies can be applied (in whole or in part) to the issues that were raised in the scoped-scoping step. In addressing these issues, two main questions should be answered: What are the limitations of the HCM methodologies? Can the limitations be overcome? Limitations of the existing HCM methodologies for each facility type are identified in the procedural chapters of Volumes 2 and 4 of this manual. If it is determined that an alternative tool is needed or advisable, then the most appropriate tool must be selected.

Selecting a Traffic Analysis Tool

Every traffic analysis tool, depending on the application, has its own strengths and weaknesses

Each analytical or simulation model, depending on the application, has its own strengths and weaknesses. It is important to relate relevant model features to the needs of the analysis and determine which tool satisfies those needs to the greatest extent. Both deterministic and simulation-based tools could be candidates for overcoming HCM limitations. In most cases, however, deterministic tools will exhibit limitations similar to the HCM procedures, which

AR0073956

are also deterministic. Deterministic tools also tend to work at the same macroscopic level as the HCM. The main applications for alternative deterministic tools fall into the following categories.

- Signal-timing plan design and optimization,
- Proprietary deterministic models that offer features not found in the HCM,
- Proprietary tools that exchange data with other traffic analysis software, and
- Roundabout analysis tools that deal with geometric and operational parameters beyond the scope of the HCM.

Simulation tools will generally be chosen to deal with situations that are too complex to model as a deterministic process. The balance of this discussion deals primarily with microscopic simulation tools.

Model Development Environment and Process

The manner in which the modeling logic was developed is an important consideration in the selection of a traffic analysis tool. The credibility of results from a simulation model depends on the process by which it was designed, implemented, and tested. A comprehensive document [14] describes "a formal process used to verify the model's reproducibility of traffic conditions in the development of a traffic flow simulation model." The intent is to prescribe a set of requirements to which all tools should conform. There is no attempt to compare the merits of different tools.

The proper simulation model development process is described in terms of the following steps. The desirable attributes of each of these steps are described:

- Determination of model specifications,
- Conformance of the model operation principles,
- Programming and debugging,
- Verification using virtual data, and
- Verification using actual data.

The traffic phenomena to be modeled through simulation are identified, and the theoretical basis for dealing with each one in a traffic model is described:

- Generation of vehicles,
- Bottleneck capacity or saturation flow rate at a link's downstream end,
- Driving and elimination of breakdown and shock wave propagation speed,
- Capacity of the merge/diverge area and the merge/diverge ratio,
- Decrease in the left-turn capacity due to opposing traffic in a signalized intersection, and
- Route selector behavior.

Users who are unfamiliar with the operation of their candidate simulation tools may wish to consult this document for informational purposes.

AR0073957

Key model features to consider

Model Capabilities

A review of modeling capabilities is probably the most important aspect of selecting a simulation tool. Simulation model results may be of no value if the model is not capable of addressing the project-scoping issues raised in the initial step. Some key features can be used to evaluate a model's capabilities, such as size of network, network representation, traffic representation, traffic composition, traffic operations, traffic control, and model output.

- *Size of network.* Most tools limit the size of network that can be analyzed and the number of vehicles that can be accommodated. The key network parameters limited by the tool include number of nodes, number of links, number of lanes per link, and number of signalized or signal-controlled intersections.
- *Network representation.* Network representation refers to the tool's ability to represent the network geometrics for urban streets, freeways, rural highways, or any combination, ranging from simple intersections to grid networks. For urban streets, major geometric elements include lane channelization at intersections, turning pockets, and bus bays and stops. For freeways, major geometric elements are acceleration lanes, deceleration lanes, auxiliary lanes, on-ramps, off-ramps, lane additions, lane drops, horizontal curvature, and grade. Elements for rural highways include grade, curvature, passing and no-passing zones, and sight distance for overtaking and passing.
- *Traffic representation.* The representation of lane traffic flows in the model, especially the level of aggregation, is an important consideration. Because of their microscopic and stochastic nature, microscopic models can simulate sophisticated vehicle movements, allowing analysts to perform complex traffic analyses such as those for weaving areas. In contrast, mesoscopic and macroscopic models are generally not appropriate for evaluating complex traffic conditions, since they use aggregate measures of flow or density to describe vehicle movements.
- *Traffic composition.* Traffic composition represents the mix of cars, buses, trucks, carpools, and bicycles in the network and is used to incorporate the differences in performance characteristics among types of vehicles and modes. Special attention needs to be given to the selection of the analysis tool when networks with dedicated accommodation for nonautomobile modes are involved.
- *Traffic operations.* The model should be capable of representing real-world traffic operations such as ramp merging, diverging, and weaving maneuvers at interchanges, high occupancy-vehicle lanes, bus transit operations, lane channelization at intersections, lane restrictions, lane blockages, and parking activities.
- *Traffic control.* For street intersections, control methods include yield signs, two-way STOP signs, all-way STOP signs, pretimed signals, actuated signals, real-time traffic-adaptive control signals, and traffic-responsive control systems. Those commonly used for freeway on-ramps include pretimed control, demand and capacity control, occupancy control, speed

AR0073958

control, high occupancy vehicle priority at ramps, integrated (network) ramp control, ramp-metering optimization, and dynamic real-time ramp-metering control with flow prediction capabilities. Signal coordination between traffic signals or between on-ramp signals and traffic signals on adjacent streets may also need to be considered.

- *DTA features.* When a network involves multiple routes that present a choice to the driver, the model must employ dynamic assignment logic to distribute the vehicles over the available paths in a realistic way. Simulation models offer varying degrees of DTA formulation and may allow for various influencing factors to be included in the decision process to reflect driver behavior. DTA models are discussed in more detail later in this chapter.
- *Other ITS devices.* In addition to the ITS elements in the traffic control category, tools may be able to model the effects of other ITS devices, such as in-vehicle navigation systems, dynamic message signs, incident management, small work zones, or intervehicle communication technologies.
- *Real-time process control features.* Many tools offer the ability to communicate directly with other processes invoked in either hardware or software. Examples include intersection signal controllers and large-scale network traffic management systems. Most highway capacity analysis projects will not require features of this type. However, when complex networks with ITS elements are involved, the ability of a simulation tool to communicate directly with the outside world might become a significant factor in the selection of the proper tool.

Above all, the analyst should review the user's guide for the selected tool to get a more detailed description of its characteristics.

User Interface

User interface considerations

The user interface includes all of the features of a tool that supply input data from the user to the model and output data from the model to the user. Simulation tools vary in the nature of their user interface. To some extent, the suitability of the user interface is a matter of individual preference. However, a highly developed user interface can offer a better level of productivity for larger and more repetitive tasks. Selection criteria related to the user interface include

- The amount of training needed to master its operation,
- The extent to which it contributes to productive model runs,
- The extent to which it is able to import and export data between other processes and databases, and
- Special computational features that promote improved productivity.

The following are the principal elements associated with the user interface:

- *Inputs.* Most of the inputs required by the model will be in the form of data. In most cases, the input data will be entered manually. Most tools offer some level of graphic user interface to facilitate data entry. Some tools also offer features that import data directly from other sources.

AR0073959

- *Outputs.* Two types of outputs are available from simulation tools: graphics files and static performance measures. Graphics files provide graphics output, including animation, so that users can visually examine the simulation model results. Static performance measures provide output for numerical analysis. Both types of outputs may be presented directly to the user or stored in files or databases for postprocessing by other programs.
- *Multiple-run support.* The stochastic nature of simulation models requires multiple runs to obtain representative values of the performance measures. Chapter 7, Interpreting HCM and Alternative Tool Results, provides guidance on the number of runs required under specific conditions. The ability of a tool to support multiple runs is an important selection criterion. Multiple-run support includes processing functions that perform a specified number of runs automatically and postprocessing functions that accumulate the results from individual runs to provide average values and confidence intervals.

Consider the kind of data required and the availability of the data in selecting a tool.

Data Availability

The next criterion identifies data requirements and potential data sources so that the disparity between data needs and data availability can be identified. In general, microscopic models require more intensive and more detailed data than do mesoscopic and macroscopic models. Three different types of data are required to make the application of the traffic simulation model successful: data for model input, data for model calibration, and data for model validation.

Data for Model Input

The basic data items required to describe the network and the traffic conditions to be studied can be categorized into four major groups:

1. *Transportation network data.* Simulation tools incorporate their network's representation into the user interface, and some differences are observed among different tools. Most simulation models use a link-based scheme in which links represent roadway segments that are connected in some manner. The required link data include endpoint coordinates, link length, number of lanes per link, lane additions, lane drops, turning pockets, lane channelization at intersections, grade, and horizontal curvature. The connector data describe the manner in which the links are connected, including the permissible traffic movements, type of control, and lane alignment.
2. *Traffic control and ITS data.* Detailed control data should be provided for all control points, such as street intersections or freeway on- and off-ramps. Sign controls include YIELD signs, two-way STOP signs, and all-way STOP signs. Signal controls include pretimed signals, actuated signals, or real-time traffic-adaptive signals. Ramp-metering control methods include all of the modes described earlier. Timing data are required for all signal controls. Detector data such as type and location of the detector are required for actuated and traffic-adaptive signals. Any special ITS

AR0073960

features involved in a project will create a need for additional data describing their parameters.

3. *Traffic operations data.* To represent the real-world traffic environment, most simulation tools take link-specific operations data as input, such as parameters that determine roadway capacity, lane use, lane restriction, desired free-flow speed, high-occupancy-vehicle lanes, parking activities, lane blockages, and bus travel operations.
4. *Traffic demand data.* Different tools may require traffic demand data in different formats. The most commonly used demand data are traffic demand at the network boundary or within the network, traffic turning percentages at intersections or freeway junctions, O-D trip tables, path-based trips between origins and destinations, and traffic composition.

Data for Model Calibration

Calibration adjusts a model's vehicle, driver, and other characteristics so that the model can reasonably represent the traffic environment being analyzed.

Calibration was defined previously as the process by which the analyst selects the model parameters that cause the model to best reproduce field-measured local traffic operations conditions. Vehicle and driver characteristics, which may be site-specific and require calibration, are the key parameters. These data take the form of scalar elements and statistical distributions that are represented by the model. In general, simulation models are developed and calibrated on the basis of limited site-specific data. The development data may not be transferable and therefore may not accurately represent the local situation. In that case, the model results should be interpreted with caution, and the default parameters that must be overridden to better reflect local conditions should be identified. Most simulation tools allow the analyst to override the default driver behavior data and vehicle data to better match local conditions, thereby allowing for model calibration. The calibration process should be documented, traceable, and reproducible to promote a robust analysis.

1. *Driver behavior data.* Driver behavior is not homogeneous, and thus different drivers may behave differently in the same traffic conditions. Most microscopic models represent stochastic or random driver behavior (from passive to aggressive drivers) by taking statistical distributions of behavior-related parameters such as desired free-flow speed, queue-discharge headway, modeling parameters for lane changing and car following, and driver response to advance information and warning signs.
2. *Vehicle data.* Vehicle data represent the characteristics and performance of the types of vehicles in the network. Different vehicle types (e.g., cars, buses, single-unit trucks, semitrailers) have different characteristics and performance attributes. They vary in terms of vehicle length, maximum acceleration, maximum deceleration, emissions rate, and fuel consumption rate. All traffic simulation tools provide default vehicle characteristics and performance data. These data need to be overridden only when the local vehicle data are known to be different from the default data provided by the tool or when the default values do not provide reasonable results.

AR0073961

Data Sources

Data collection is costly. Analysts should explore all possibilities to leverage previously collected data. The analyst should identify which data are currently available and which data need to be collected in the field. Most static network, traffic, and control data can be collected from local agencies. Such data include design drawings for geometrics, signal timing plans, actuated controller settings, traffic volume and pattern, traffic composition, and transit schedules.

Ease of Use

Simulation models use assumptions and complex theories to represent the real-world dynamic traffic environment. Therefore, an input–output graphical display and debugging tools that are easily understandable are important criteria to consider in selecting a tool. Although ease of use is important in a simulation tool, the fact that a particular tool is easy to use does not necessarily imply that it is the correct choice. The following five criteria can be considered in assessing the ease of use of a simulation tool:

- *Preprocessor*: input data handling (user-friendly preprocessor);
- *Postprocessor*: output file generation for subsequent analysis;
- *Graphic displays*: graphic output capabilities, both animated and static;
- *Online help*: quality of online help support; and
- *Calibration and validation*: ability to provide guidelines and data sets for calibration and validation.

Required Resources

The following issues with regard to resources should be addressed in selecting a traffic analysis tool:

- *Costs of the tool*: Examples are costs for data collection and input preparation, hardware and software acquisition, and model use and maintenance.
- *Staff expertise*: Intelligent use of the tool is the key to success. The analyst should understand the theory behind the model to eliminate improper use and avoid unnecessary questions or problems during the course of the project.
- *Technical support*: Quality and timely support are important in the acquisition of a tool.

User Applications and Past Performance

Credibility and user acceptance of a tool are built on the tool's past applications and experiences. No tool is error-free when first released, and all require continuous maintenance as well as periodic enhancements.

Verification and Validation

It is important to assess how extensively a given model has been verified. In many cases, but not all, simulation models are also validated as part of the formulation and development process. Certainly those that have been validated

AR0073962

are nominally better to use than those that have not been validated. Generally, models that have been in use for some time are likely to have been assessed and validated by various researchers or practitioners who are using them. It is useful to look for evidence of validation in professional journals and periodicals.

APPLICATION GUIDELINES FOR SIMULATION TOOLS

This section presents general guidance for the use of simulation-based traffic analysis tools for capacity and performance analysis. More detailed guidance for the application of these tools to specific facilities is presented in the procedural chapters of Volumes 2 and 3. Additional information, including sample applications, may be found in Volume 4 and in the *Traffic Analysis Toolbox* (*5*) mentioned earlier in this chapter.

After the project scope has been determined and the tool has been selected, several steps are involved in applying the tool to produce useful results.

Assembling Data

Data assembly involves collecting the data required (but not already available) for the selected tool. Data collection is costly. Analysts should capitalize on previous modeling efforts and identify data available through local agencies. When existing data are assembled, users should develop a comprehensive plan for collecting data that are missing. In some cases, a pilot data collection effort may be needed to ensure that the developed data collection plan is workable before a full-scale effort is conducted.

An important part of the data assembly process is a critical review of all data items to ensure the integrity of the input data set. Of special concern are the continuity of traffic volumes from segment to segment and the distribution of turning movements at intersections and ramp junctions. Each data item should be checked to ensure that its value lies within reasonable bounds.

Entering Data

Once all required data are in hand, the next step is to create the input files in a format required by the selected tool. The following are the most commonly used methods for creating input files.

- *Importing from a traffic database.* Many analysts have large amounts of data in a variety of formats for the general purpose of traffic analysis. Such databases can be used to create input files.
- *Converting from the existing data of other tools.* Many traffic models use the same or similar data for modeling purposes so that these data may be shared. Some traffic simulation tools are accompanied by utility programs that allow the user to convert data into input files required by other tools.
- *Entering the data from scratch.* Many traffic analysis tools have their own specific input data preprocessors, which aid the analyst with input data entry and review. These advanced features of the input data preprocessor eliminate cumbersome coding efforts. In addition, some input preprocessors include online help features.

AR0073963

Calibrating and Validating Models

The model should be run with the data set describing the existing network and traffic scenarios (i.e., the baseline case), and the simulation results should then be compared with the observed data collected in the field." The primary objective of this activity is to adjust the parameters in the model so that simulation results correspond to real-world situations.

Several critical issues must be addressed when an initial simulation model run is constructed for the baseline case. First, the model should be able to represent the initial state of the traffic environment before any statistics can be collected for analysis. Second, the model should be long enough to cover the entire analysis period. Third, if the model can handle time-varying input, the analyst should specify, to the extent possible, the dynamic input conditions that describe the traffic environment. For example, if 1 h of traffic is to be simulated, the analyst should always specify the variation in demand volumes over that hour at an appropriate level of detail rather than specifying average, constant values of volume.

Finally, the analyst should know how to interpret the simulation model results, draw inferences from them, and determine whether they constitute a reasonable and valid representation of the traffic environment. Given the complex processes taking place in the real-world traffic environment, the user must be alert to the possibility that the model's features may be deficient in adequately representing some important process; that the specified input data, calibration, or both are inaccurate or inadequate; that the results provide a level of insufficient detail to meet the project objectives; that the statistical analysis of the results is flawed (as discussed in the following section); or that the model has bugs or that some of its algorithms are incorrect, thereby necessitating revision. If animation displays are provided by the model, this option should always be exercised to identify any anomalies.

If the simulation model results do not reasonably match the observed data collected in the field, the user should identify the cause-and-effect relationships between the observed and simulated data and the calibration parameters and perform calibration and validation of the model. Information on calibration and validation of models may be found in the *Freeway Analysis* Section (F-3) and in the references listed in Volume 4.

Special Considerations for DTA

The term "traffic assignment" traditionally refers to the process of computing path demands, or path input flows, given a network and an O-D demand matrix (trip table). In macroscopic simulation models, this process is implemented as a route-choice model that is executed independently for each driver (vehicle) in the simulation. Using explicit routes to move vehicles through the simulation obviates the use of turning proportions at nodes. Routes and route flows may also be implicitly represented in a model by splitting rates, which are turning proportions at nodes by destination. Route flows can have a significant impact on model outputs such as LOS, since they play a key role in determining the local traffic demand on any given section of road.

AR0073964

Regardless of the implementation, traffic assignment is the way in which travel demand is defined in the form of an OD matrix (static or time-varying) and multiple routes are available for some OD pairs. It is particularly relevant when congestion affects the travel times on some of these routes. DTA produces time-varying path flows (or splitting rates) by using a dynamic traffic model that is either mesoscopic or microscopic. DTA models normally permit the demand matrix to be time-varying as well. The assignment model (routing decision) is based on a specific objective, which is predominantly the minimization of travel time, but will also take other factors such as travel cost (e.g., tolls or congestion pricing) and travel distance into consideration.

A fundamental issue concerning the role of travel time in route choice is that the actual travel time from origin to destination cannot be known in advance; it results from the collective route choices of all the drivers. Thus, the input to the routing decision (travel time) depends on the decision itself (route choice), forming a logical cycle. This type of problem can be solved with an iterative algorithm that repeats the simulation several (or many) times over, imitating the day-to-day learning process of drivers in the real world. At each iteration (or "day") the assignment is adjusted until the route-choice decisions are consistent with the experienced travel times; this is referred to as the user-optimal solution. In practice, an approximation to the user-optimal route flows is often determined by using a "one-pass" (noniterative) assignment in which drivers repeatedly reevaluate their routes during a single simulation run. The choice of method depends on network characteristics and modeling judgment.

The assignment (routing) component of a DTA model may be deterministic or stochastic in nature, independent of whether the traffic model is deterministic or stochastic. In general, both approaches can produce good results as long as they produce route choices that are consistent with the routing objective, for example, the minimization of generalized travel cost. The generalized cost is determined from the combination of a range of factors, such as travel time, travel distance, and direct costs (e.g., tolls), by applying relative weights to each of these factors, which typically differ by user class.

DTA applications are not trivial. Whereas single-route applications are typically implemented by one analyst, DTA applications to large-scale systems are more likely to involve a team of analysts with a broader range of skills and experience. A comprehensive reference on DTA has been created by the Transportation Research Board's Committee on Network Modeling [15].

Analyzing Output

Proper output analysis is one of the most important aspects of any study using a simulation model. A variety of techniques are used, particularly for stochastic models, to arrive at inferences that are supportable by the output.

When the model is calibrated and validated, the user can conduct a statistical analysis of the simulation model results for the baseline case with calibration parameters. If the selected simulation model is stochastic in nature, simulation model results produced by a single run of the model represent only point estimates of the sample population. Typical goals of data analysis using output

AR0073965

from stochastic-model experiments are to present point estimates of the performance measures and to form confidence intervals around these estimates. Point estimates and confidence intervals for the performance measures can be obtained from a set of replications of the system by using independent random number streams. The analyst should refer to previous studies for details on the design and analysis of stochastic simulation models in the *Traffic Analysis Toolbox* (*7*, *8*) and in Volume 4 of the HCM.

Analyzing Alternatives

When satisfactory simulation model results are obtained from the baseline case, the user can prepare data sets for alternative cases by varying geometry, controls, and traffic demand. If the model is calibrated and validated on the basis of the observed data, values of the calibrated parameters should also be used in the alternatives analysis, assuming that driver behavior and vehicle characteristics in the baseline case are the same as those in the alternative cases.

Traffic simulation models produce a variety of performance measures for alternatives analysis. As discussed previously, the user should identify what model performance measures and level of detail are anticipated. These performance measures, such as travel time, delay, speed, and throughput, should be quantifiable for alternatives analysis. Some tools provide utility programs or postprocessors, which allow users to perform the analysis easily. If animation is provided by the tool, the user can gain insight into how each alternative performs and can conduct a side-by-side comparison graphically.

APPENDIX A: DEVELOPING LOCAL DEFAULT VALUES

Default values are generally used for HCM applications that do not require the accuracy provided by a detailed operational evaluation.

A default value is a constant to be used in an equation as a substitute for a field-measured (or estimated) value. Default values can be used for input parameters or calibration factors. The value selected should represent a typical value for the conditions being analyzed. Default values are generally used for planning, preliminary engineering, or other applications of the HCM that do not require the accuracy provided by a detailed operational evaluation (*A-1*). They can be applied to any of the modes addressed by the HCM.

Default values should not be applied for input variables that can significantly influence the analysis results.

Local default values can be developed by conducting measurements of "raw data" in the geographic area where the values are to be applied. Typically, default values are developed for roadway or traffic characteristics to identify typical conditions of input variables for planning or preliminary engineering analysis. Default values should not be applied for input variables that can significantly influence the analysis results. For interrupted-flow facilities, these sensitive input variables include peak hour factor, traffic signal density, and percent heavy vehicles. For uninterrupted-flow facilities, these sensitive input parameters include free-flow speed, peak hour factor, and specific grade. In developing generalized service volume tables for daily service volumes, the *K*- and D factors selected must be consistent with measured local values.

When local default values are developed, the raw data should be collected during the same time periods that will be used for analysis—typically during weekday peak periods. In some cases, the peak 15 min period is recommended as the basis for computation of default values because this time period is most commonly used for capacity and LOS analysis.

Input parameters that describe the facility type, area type, terrain type, and geometric configuration (such as lane width, segment length, and interchange spacing) are usually available to the analyst. Default values for these parameters should not be used.

APPENDIX B: DEVELOPING LOCAL SERVICE VOLUME TABLES

INTRODUCTION

This appendix focuses on the automobile mode. To the extent that modal analysis is an input to nonautomobile mode LOS procedures, the material could also be applied to nonautomobile modes.

As discussed in the body of this chapter, service volume tables can provide an analyst with an estimate of the maximum number of vehicles a system element can carry at a given LOS. The use of a service volume table is most appropriate for certain planning applications in which evaluation of every segment or node within a study area is not feasible. Once potential problem areas have been identified, other HCM tools can be used to perform more detailed analyses for just those locations of interest.

To develop a service volume table, the analyst needs to develop a default value for each of the input parameters. The choice of default value can have a significant impact on the resulting service volume for a given LOS. For this reason, great care should be used to develop default values that the analyst believes are most appropriate for the local condition. When results are particularly sensitive to a particular input parameter, a range of default values should be considered for that parameter. The application of sensitivity analyses is discussed in more detail in Chapter 7, Interpreting HCM and Alternative Tool Results.

A specific roadway's characteristics are unlikely to match exactly the default values used to generate a service volume table. Therefore, conclusions drawn from such tables should be considered to be rough approximations.

When the service volume table is applied, it is important to recognize that not all of the input parameters for the various roadway segments being evaluated are likely to match the default inputs. Accordingly, conclusions drawn from the application of service volume tables should be considered to be, and presented as, rough approximations.

TABLE CONSTRUCTION PROCESS

Service volume tables can be generated for a given system element by selecting appropriate input parameter values and applying software to back-solve for the maximum volume associated with a particular LOS. The procedure is as follows (Ref. 7):

1. Determine all of the nonvolume default values to be used in developing the service volume table (e.g., number of lanes, peak hour factor, percentage of heavy vehicles, area type, *K*- and *D*-factors), in accordance with the guidance in Appendix A. Repeat the following steps for each system element and area category.
2. Identify the threshold value associated with the system element's MOE for LOS A by using the LOS exhibit in the Volume 2 or Volume 3 chapter that covers that system element. For example, a density of 11 pc/mi/ln is the maximum density for LOS A for a basic freeway segment.
3. Compute the MOE for a volume of 10 veh/h for an hourly volume table, or 100 veh/h for a daily volume table. If the result exceeds the LOS A threshold value, then LOS A is unachievable. Repeat Steps 2 and 3 for the next LOS (e.g., LOS B) until an achievable LOS is found, then continue with Step 4.

AR0073970

4. Adjust the input volume until the highest volume that achieves the LOS is found. Test volumes should be a multiple of at least 10 for hourly volume tables and a multiple of at least 100 for daily volume tables. If the table is being constructed by manually applying software, the analyst can observe how closely the MOE result is converging toward the LOS threshold value and can select a test volume for the next iteration accordingly. If the table generation function is being added to software, the automated method described below can be used to converge on the service volume progressively.
5. Identify the threshold value for the next LOS and repeat Steps 4 and 5 until threshold volumes (or unachievability) have been determined for each LOS.
6. If a daily volume table is being created, divide the identified hourly threshold volumes by the selected *K*- and *D*-factors and round down to a multiple of at least 100.
7. If desired, change the input value used for one of the input parameters (e.g., number of lanes) and repeat Steps 2 through 5 as many times as needed to develop service volumes for all desired combinations of input values.

The following is an automated method for finding threshold values:

1. Let the first achievable test volume be labeled Vol 1.
2. Select a second iteration volume (label this Vol 2) by doubling Vol 1.
3. Compute the MOE value for Vol 2.
4. If the resulting MOE value is lower than the LOS threshold, replace Vol 1 with Vol 2 and select a new Vol 2 with double the current Vol 2 value. Repeat Steps 3 and 4 until the MOE result is greater than the desired LOS threshold.
5. Use the bisection method described below (*B-1*) or another more efficient numerical method to converge on the service volume.
6. Compute the volume halfway between Vol 1 and Vol 2. Label this volume Vol 3.
7. Compute the MOE value for Vol 3.
8. If the MOE result for Vol 3 is greater than the desired LOS threshold, replace Vol 2 with Vol 3.
9. If the LOS result for Vol 3 is lower than the desired LOS threshold, replace Vol 1 with Vol 3.
10. Is the range between Vol 1 and Vol 2 acceptable? If yes, stop and use the average of Vol 1 and Vol 2. If not, repeat Steps 6 through 9.
11. If an hourly volume table is being generated, round down the result of Step 10 to a multiple of at least 10. If a daily volume table is being generated, divide the result of Step 10 by the selected *K*- and *D*-factors and round the result down to a multiple of at least 100.

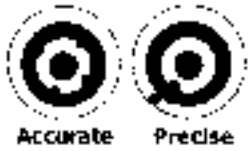
Uncertainty, sensitivity, accuracy, and precision are related concepts that need to be considered when interpreting and presenting model results



The evolution of computer software, with an ever-increasing variety of tools available, makes it easy for analysts to conduct transportation analyses and to consider a wide variety of factors in doing so. One thing that has not changed, however, is the analyst's responsibility to have a full understanding of the methodologies used by the selected analysis tools—including the level of uncertainty in the tools' results—in order to make well-informed recommendations based on the analysis results and to communicate those results to others. As tools become more complex and sophisticated, the analyst's challenge increases.

Chapter 7, Interpreting HCM and Alternative Tool Results, begins with a discussion of the uncertainty in model outputs that results from (a) uncertainty in a model's inputs, (b) uncertainty in the performance measure estimate produced by a model, and (c) imperfect model specification, as which a model may not fully account for all the factors that influence its output. Uncertainty in model inputs can result from the *variability* of field-measured values, from the uncertainty inherent in forecasts of future volumes, and from the use of default values. The *accuracy* of a model's results is directly related to its uncertainty. A model that incorporates more factors may appear on the surface to be more accurate, but if the inputs relating to the added factors are highly uncertain, accuracy may actually be decreased. Analysts should also carefully consider the *precision* used in presenting model results to avoid implying more accuracy than is warranted.

Alternative tools often provide performance measures that have the same, or similar, names as HCM measures but that are defined differently

When both HCM-based and alternative tools are used in an analysis or when a performance measure produced by an alternative tool is being used to determine level of service (LOS), analysts should take care to ensure that the measures produced by the alternative tool are defined in the same way as the HCM measure. Different tools use different definitions for similarly named measures, which may lead to inaccurate conclusions if the differences are not accounted for properly. Chapter 7 provides guidance on defining, measuring, and comparing key outputs of alternative tools when such outputs are intended to be used with or compared with those of the HCM.

Chapter 7 concludes with guidance on the number of significant digits to use in displaying HCM results and on ways to present HCM results to facilitate their interpretation by technicians, decision makers, and the general public.

AR0073975

2. UNCERTAINTY AND VARIABILITY

UNCERTAINTY AND VARIABILITY CONCEPTS

Model outputs—whether from the HCM or alternative tools—are estimates of the "true" values that would be observed in the field. Actual values will be within some range of the estimated value.

The performance measure results produced by traffic models—both HCM-based and alternative tools—are estimates of the "true" values that would be observed in the field. These estimates are not exact, however—they are subject to statistical *uncertainty*, in which the true value of a given measure lies within some range of the estimated value.

Sources of variability in correctly measured values used as model inputs. Measurement error is yet another form of uncertainty.

To illustrate the lack of exactness, consider the *variability* in measured values, such as traffic volume inputs. There are several types of variability:

- *Temporal variability*, in which measured values, such as hourly traffic volumes, vary from day to day or month to month at a given location;
- *Spatial variability*, in which measured values, such as the percentage of trucks in the traffic stream, vary from one location to another within a state or vary from one state to another; and
- *User perception variability*, in which different users experiencing identical conditions may perceive those conditions differently—for example, when asked to rate their satisfaction with those conditions.

Sources of uncertainty in model outputs

Chapter 5, Quality and Level-of-Service Concepts, noted that model outputs are subject to three main sources of uncertainty (1):

1. Uncertainty in model inputs, such as variability in measured values, measurement error, uncertainty inherent in future volume forecasts, and uncertainty arising from the use of default values;
2. The uncertainty of the performance measure estimate produced by a model, which in turn may rely on the output of another model that has its own uncertainty; and
3. Imperfect model specification—a model may not fully account for all the factors that influence the model output.

Uncertainty cannot be eliminated, but its effects can be reduced through a variety of techniques.

Although uncertainty cannot be eliminated, its effects can be reduced to some extent. For example, the HCM's concept helps to dampen the effects of uncertainty by presenting a range of service-measure results as being reasonably equivalent from a traveler's point of view. The use of a design hour, such as the 30th-highest hour of the year, also reduces uncertainty, as the variability of the design hour volume is much lower than the variability of individual hourly volumes throughout the year (1). Measured values will have more certainty than default values will, and multiple observations of a model input will have more certainty than a single observation. Sensitivity analyses—described later in this section—and other statistical techniques (2) can be used to test the impact of changes in model inputs on model outputs.

AR0073976

SOURCES OF UNCERTAINTY

Input Variables

HCM procedures and alternative tools typically require a variety of input data. Depending on the situation, there are up to three ways an analyst can provide these inputs. Listed in order of increasing uncertainty, they are (a) direct measurement, (b) locally generated default values, and (c) national default values suggested by the HCM or built into an alternative tool. Default values may not reflect spatial and temporal variability—national defaults to a greater extent than local defaults—because the mix of users and vehicles varies by facility and by time of day and because drivers' behavior varies depending on their familiarity with a facility and prevailing conditions. Direct measurements are subject only to temporal variability, as the measurement location's site-specific differences will be reflected in the observed values.

Traffic volume variability from day to day and unknowns associated with future year traffic volume forecasts are among the primary sources of uncertainty.

Day-to-day variability in traffic volume is a primary source of uncertainty in traffic analyses (1, 3). Future-year volumes are subject to higher degrees of uncertainty as one forecasts farther into the future because of unknowns about developmental patterns and timing, the timing of changes or additions to other parts of the transportation system, and changes in use of particular travel modes. Other input variables whose uncertainty has been studied in the literature are saturation flow rates (4), critical headways, and follow-up time (5).

Model Accuracy

Model Development

Many HCM models are based on theoretically derived relationships, which include assumptions and contain parameters that must be calibrated on the basis of field data. Other HCM models are primarily statistical. The accuracy of these models can be described in terms of standard deviations, coefficients of determination of linear regression (R^2), and other statistical measures.

Only some of the older HCM models (i.e., those first appearing in the HCM2000 or earlier editions) have well-documented measures of uncertainty. On occasion, the Transportation Research Board's Committee on Highway Capacity and Quality of Service has exercised its judgment in modifying models to address illogical results (e.g., at boundary conditions) or to fill in gaps in small databases. In such cases, the "true" uncertainty of the entire model is virtually impossible to quantify. In contrast, most models developed for the HCM 2010 have documented measures of uncertainty. This information is provided in the original research reports for the HCM methodologies, which can be found in the Technical Reference Library in Volume 4.

Documentation of the uncertainty inherent in HCM models can be found in the models' original research reports, located in the Technical Reference Library in Volume 4.

Nested Algorithms

In many methodologies, the algorithm used to predict the final service measure relies on the output of another algorithm, which has its own uncertainty. Thus, the uncertainty of the final algorithm is compounded by the uncertainty in an input value derived from another algorithm.

AR0073977

In Chapter 12, Freeway Weaving Segments, for example, the prediction of weaving and nonweaving speeds depends on the free-flow speed and the total number of lane changes made by weaving and nonweaving vehicles. Each of these inputs is a prediction, based on other algorithms, each having its own uncertainty. As additional examples, the urban street facility and freeway facility procedures are built on the results of underlying segment and (for urban streets) point models, the outputs of which have their own associated uncertainties.

Traveler Perception

The HCM 2010 introduces several traveler perception-based models for estimating LOS for the bicycle, pedestrian, and transit modes. In addition, Chapter 17, Urban Street Segments, provides an alternative traveler-perception model for the automobile mode to help support multimodal analyses. These models produce estimates of the average LOS travelers would state for a particular system element and mode. However, people perceive conditions differently, which results in a range of responses to be covering the full LOS A to F range) for a given situation. As with other models, statistical measures can be used to describe the variation in the responses as well as the most likely response (6).

Different people will have different levels of satisfaction for identical conditions.

Additional Documentation

In addition to the uncertainty values given in the original research for HCM methods, the uncertainty of a number of current HCM models has been studied in the literature. These studies include unsignalized intersections (6, 7, 8), two-lane highways (9), and other uninterrupted-flow facilities (10).

Model Specification

A final potential source of uncertainty is an incomplete model specification, in which not all the factors that influence a model's result are reflected in the model's parameters. (An inaccurate specification, in which the wrong parameters are included in the model, also falls into this category.) The significant increase in the size of the HCM with each new edition, along with the complexity of its procedures, is due in part to users' desire for HCM models to account more fully for factors that influence the HCM's performance measures.

A more complex model is not necessarily a more accurate model.

However, a diminishing-returns principle also applies to model complexity. Each new variable added to a model brings with it uncertainty related to both the model's parameters and its input values. This additional complexity may not be warranted if the model's final output becomes more uncertain than it was before, even if the model appears to be more accurate by taking additional factors into account. Model complexity that leads to better decision making is justified; complexity that does not is best avoided (11).

SENSITIVITY ANALYSIS

One way to address the uncertainty inherent in a performance measurement estimate is to conduct a sensitivity analysis, in which key model inputs are individually varied over a range of reasonable values and the change in model outputs is observed. It is important for analysts to have a good understanding of

AR0073978

the sensitivity of model inputs, and special care should be taken in selecting appropriate values for particularly sensitive parameters. It is also important for analysts and decision makers to understand the sensitivity of model outputs (numerical values or the LOS letter grade) to changes in inputs, particularly volume forecasts, when they interpret the results of an analysis.

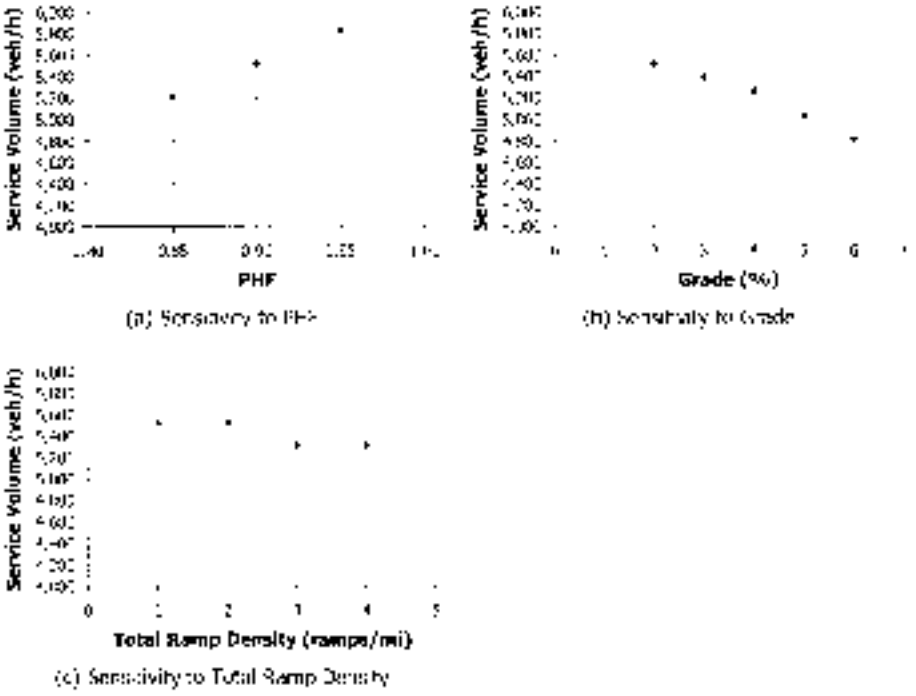
Sensitivity analysis is a useful technique for observing how model outputs change in response to changes in model inputs.

Exhibit 7-1 illustrates a sensitivity analysis for selected inputs to the basic freeway segment method. A typical application would be a planning study for a future freeway, where not all the inputs are known exactly. The output being tested is the service volume (in vehicles per hour, veh/h) for LOS D (i.e., the highest volume that results in LOS D, given the other model inputs). The following inputs were held constant in all three examples.

- Lane width: 12 ft
- Percent trucks: 3%
- Driver population factor: 1.00
- Number of lanes per direction: 3
- Shoulder width: 6 ft
- Grade length: 1 mi

In each example, one of the following inputs was varied, while the other two were held constant. The varied input differs in each example.

- Peak hour factor (PHF): 0.90, varied from 0.80 to 0.95 in Exhibit 7-1(a)
- Grade: 2%, varied from 1% to 6% in Exhibit 7-1(b)
- Total ramp density: 2 ramps/mi, varied from 1 to 4 ramps/mi in Exhibit 7-1(c)



(a) Sensitivity to PHF

(b) Sensitivity to Grade

(c) Sensitivity to Total Ramp Density

Exhibit 7-1
Example Sensitivity Analysis for Selected Basic Freeway Segment Model Inputs

AR0073979

If varying a single input parameter within its reasonable range results in a 0% to 10% change in the service measure estimate, the model can be considered to have a low degree of sensitivity to that parameter. If a 10% to 20% change in the service-measure estimate results, the model can be considered moderately sensitive to that parameter, while if a change greater than 20% results, the model can be considered highly sensitive (12).

As shown in Exhibit 7-1(a) and Exhibit 7-1(b), LOS D service volumes for basic freeway segments are moderately sensitive to both PHF and grade across the reasonable ranges of values for those inputs, with the highest service volumes 12% and 14% higher than the lowest service volumes, respectively. Consequently, particular care should be taken to select appropriate values for those inputs.

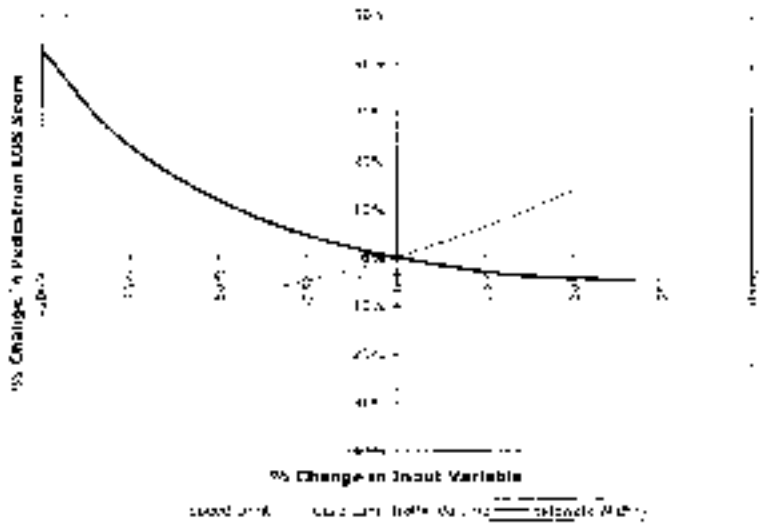
When changing the total ramp density results in a two-line speed estimate, while the same 5-mi/h range used in a particular speed–flow curve, no change in the service volume result will be seen.

Exhibit 7-1(c) shows that LOS D service volumes have a low sensitivity to total ramp density, with just a 4% range in the output volumes. Therefore, it is not essential for the assumed average ramp density value to match the future condition closely.

Exhibit 7-2 shows an alternative way to display sensitivity information, based on the pedestrian link LOS score from Chapter 17, Urban Street Segments. In this example, the number of directional lanes (1), each lane width (12 ft), and PHF (0.90) are held fixed, and it is assumed there is no bicycle lane, parking lane, or buffer between the sidewalk and the curb lane. The following inputs are varied one at time:

- Speed limit: 30 mi/h, varied from 20 to 60 mi/h;
- Curb lane traffic volume: 500 veh/h, varied from 50 to 1,000 veh/h; and
- Sidewalk width: 6 ft, varied from 0 to 10 ft.

Exhibit 7-2
Example Sensitivity Analysis of Urban Street Link Pedestrian LOS Score



The pedestrian LOS score is relatively insensitive to speed limit, moderately sensitive to sidewalk width (except when a sidewalk is not present), and highly sensitive to curb lane traffic volume. This kind of presentation works best when

AR0073980

typical values for the input variables to be tested. For near the middle of their range rather than at or near one of the extremes.

Exhibit 7-3 shows an example of testing the sensitivity of control delay, and the corresponding LOS result, at an all-way stop-controlled intersection, by varying the demand volumes used in the analysis. In the exhibit, the base volume entering the intersection on all approaches is varied within a ±15% range in 5% increments. This kind of sensitivity analysis is particularly useful in working with forecasts of volume that have a relatively high degree of uncertainty associated with them.

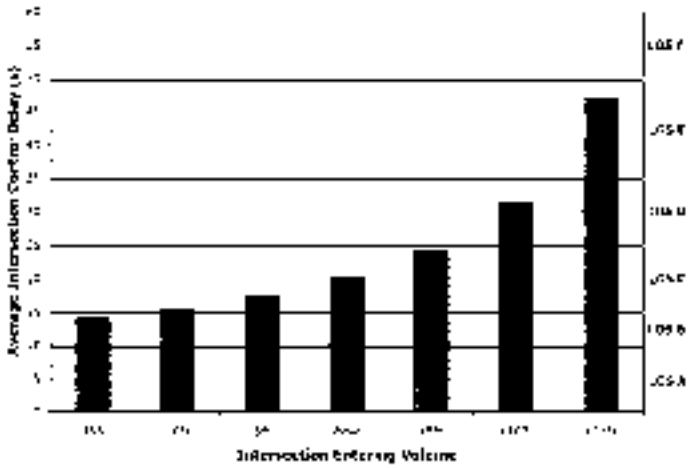


Exhibit 7-3
Example Sensitivity Analysis of All-Way Stop-Control Node Outputs Based on Varying Volume Inputs

Note: Values used in the calculations are for signalized intersections with one lane on each approach, PHF = 0.92, and 2% heavy vehicles. Base volumes are 200 through vehicles, 35 left-turning vehicles, and 35 right-turning vehicles on each approach.

As shown in Exhibit 7-3, under the base volume forecast, the intersection is forecast to operate at LOS C. If future traffic volumes are lower than forecast or as much as 5% higher than forecast, the intersection will still operate at LOS C or better. If future traffic volumes are 10% higher than forecast, the intersection will operate at LOS D. If traffic volumes are 15% higher than forecast, the intersection will operate at LOS E. If the jurisdiction's operations standard for the intersection is LOS E or better, it could be reasonably concluded that the intersection would still operate acceptably even if higher volumes than forecast were to occur. However, if the standard was LOS D or better, a closer look at the conservativeness of the volume forecasts might be needed to conclude that the intersection would operate acceptably.

Depending on the model and the specifics of the scenario being modeled, relatively small changes in model inputs can have relatively large impacts on model outputs.

ACCURACY AND PRECISION

Overview

Accuracy and precision are independent but complementary concepts. Accuracy relates to achieving a correct answer, while precision relates to the size of the estimation range of the parameter in question. As an example of accuracy, consider a method that is applied to estimate a performance measure. If the performance measure is delay, an accurate method would provide an estimate closely approximating the actual delay that occurs under field conditions. The

AR0073981

precision of such an estimate is the range that would be acceptable from an analyst's perspective in providing an accurate estimate. Such a range might be expressed as the central value for the estimated delay plus or minus several seconds.

In general, the inputs used by HCM methodologies come from field data or estimates of future conditions. In either case, these inputs can be expected to be accurate to only within 5% or 10% of the true value. Thus, the computations performed with these inputs cannot be expected to be extremely accurate, and the final results must be considered as estimates that are accurate and precise only within the limits of the inputs used.

HCM users should be aware of the limitations of the accuracy and precision of the methodologies in the manual. Such awareness will help users interpret the results of an analysis and use the results to make a decision about the design or operation of a transportation facility.

Calculation Precision Versus Display Precision

Precision in calculation allows more precision in presenting final results.

The extensive use of personal computers has allowed calculations of capacity and LOS to be carried to a large number of digits to the right of the decimal point. Because of this ease of calculation, there is a need to state clearly that the final result of calculations done manually and carried to the suggested number of significant figures might be slightly different from the result of calculations performed on a computer.

Implied Precision of Results

The typical interpretation given to a value such as 2.0 is that the value is in a precision range of two significant figures and that results from calculations should be rounded to this level of precision. The actual computational result would have been in the range of 1.95 to 2.04 by standard rounding conventions. Occasionally, particularly in the running text of the HCM, editorial flexibility allows a zero to be dropped from the number of digits. In most cases, however, the number of the digits to the right of the decimal point does imply that a factor or numerical value has been calculated to that level of precision.

AVERAGE VALUES

Unless specifically noted otherwise, HCM performance measure estimates are average (mean) values.

Unless otherwise noted or defined, numerical values are mean values for the given parameter. Thus, a measure of speed or delay is the mean value for the population of vehicles (or persons) being analyzed. Similarly, a lane width for two or more lanes is the mean (average) width of the lanes. The word "average" or "mean" is only occasionally carried along in the text or exhibits to reinforce this otherwise implicit fact. LOS threshold values, adjustment factors used in computations, and calculated values of performance measures are assumed to represent conditions that have a reasonable expectation of being observed regularly in North America as opposed to the most extreme condition that might be encountered.

AR0073982

3. DEFINING AND COMPUTING UNIFORM PERFORMANCE MEASURES

The exact definition of performance measures poses an important question, particularly when a comparison of performance measures produced by different tools is to be made. Definitions and computational methods are especially important when the LOS must be inferred from another performance measure obtained by alternative methods and applied to the thresholds presented in the HCM's procedural chapters. Often, a performance measure is given the same name in various tools, but its definition and interpretation differ.

This section identifies the performance measures commonly reported by the procedures given in Volumes 2 and 3. The concept of developing those measures from an analysis of the individual vehicle trajectories produced by microsimulation tools is introduced. The most important measures are discussed in terms of uniform definitions and methods of computation that will promote comparability among different tools. More detailed procedures for developing performance measures from individual vehicle trajectories are presented in Chapter 24, Concepts Supplemental.

PERFORMANCE MEASURES REPORTED BY HCM PROCEDURES

The key performance measures associated with each of the procedural chapters in Volumes 2 and 3 were summarized in Chapter 6, HCM and Alternative Analysis Tools. The applicability of these procedures and alternative tools was indicated for each type of facility. Exhibit 7-4 includes all the performance measures identified in Chapter 6. The service measures that determine LOS for each system element are also identified. In this section, the key performance measures are presented in terms of their definitions and computational procedures. The potential for the development of uniform performance measures from alternative tools is presented in a later section.

Exhibit 7-4
Performance Measures Reported by HCM Procedures

Chapter	Density	Speed	v/c Ratio[a]	Travel Time	Control Delay	Queue	Other Measures
10. Freeway Facilities	Yes	Yes	Yes	Yes		Yes	[b]
11. Basic Freeway Segments	Yes	Yes	Yes				
12. Freeway Weaving Segments	Yes	Yes	Yes				[c]
13. Freeway Merge and Diverge Segments	Yes	Yes	Yes				
14. Multilane Highways	Yes	Yes	Yes				
15. Two-Lane Highways		Yes	Yes				[d]
16. Urban Street Facilities		Yes		Yes	Yes		[e]
17. Urban Street Segments		Yes		Yes	Yes		[f]
18. Signalized Intersections			Yes		Yes	Yes

Notes: v/c, volume to capacity ratio; TWSC, two-way stop-controlled; AWSC, all-way stop-controlled; **bold** text indicates key measures.
[a] A v/c ratio greater than 1.00 is often used to define LOS F conditions.
[b] Vehicle miles, vehicle hours.
[c] Weaving speed, non-weaving speed.
[d] Percent time spent following.
[e] Stop rate, running time.
[f] Meeting and passing events.

AR0073983

Speed-Related Measures

Speeds are reported in several chapters of this manual:

- *Chapter 10, Freeway Facilities*, uses the average speeds computed by the other freeway procedural chapters when all segments are undersaturated. When demand exceeds capacity, the speeds on the affected segments are modified to account for the effects of slower-moving queues.
- *Chapter 11, Basic Freeway Segments*, estimates the average speed on the basis of the free-flow speed and demand volume by using empirically derived relationships.
- *Chapter 12, Freeway Weaving Segments*, estimates the average speed as a composite of the speeds of weaving and nonweaving vehicles on the basis of free-flow speed, demand volumes, and geometric characteristics. The computational procedures for estimating the actual speeds are based on the nature of the weaving segment and the origin–destination matrix of traffic entering and leaving the segment. The speed estimation processes are substantially more complex in weaving segments than in basic freeway segments.
- *Chapter 13, Freeway Merge and Diverge Segments*, estimates the average speed of vehicles across all lanes as well as the average speeds in the lanes adjacent to the ramp. The computations are based on empirical relationships specifically derived for merge and diverge segments.
- *Chapter 15, Two-Lane Highways*, treats the average travel speed (ATS) on certain classes of highways as one determinant of LOS. The ATS is determined as an empirical function of free-flow speed, demand flow rate, proportion of heavy vehicles, and grades.
- *Chapter 16, Urban Street Facilities*, uses "travel speed as a percentage of base free-flow speed" to determine LOS.
- *Chapter 17, Urban Street Segments*, also uses speed to determine LOS. The average speed is computed by dividing the segment length by the average travel time. The average travel time is determined as the sum of three components:
  1. Time to traverse the link at the running speed, which is computed as a function of the free-flow speed, demand flow rate, and geometric factors;
  2. Control delay due to the traffic control device at the end of the segment; and
  3. Midblock delay due to access points.

  The average speed applies only to arterial through vehicles and not to the traffic stream as a whole.

AR0073984

Queue-Related Measures

Queue measures are defined and computed for both interrupted- and uninterrupted-flow facilities. Queues may be defined in terms of the number of vehicles contained in the queue or the distance of the last vehicle in the queue from the end of the segment (i.e., back of queue or BOQ). The probability of the BOQ reaching a specified point where it will cause problems is of most interest to the analyst. For most purposes, the BOQ is therefore a more useful measure than the number of vehicles in the queue.

Queue measures are reported by the following procedures in this manual.

- *Chapter 10, Freeway Facilities:* Queuing on freeway facilities is generally the result of oversaturation caused by excessive demand or by bottlenecks. As such, it is treated deterministically in Chapter 10 by an input–output model that tracks demand volumes and actual volume served through the bottleneck. The propagation and dissipation of freeway queues are estimated from a three-deterministic queuing model. The shock wave speed at which queues grow and shrink is calculated from the jam density and the flow and density at capacity. Residual demand is processed in subsequent time intervals as demand levels drop or the bottleneck capacity increases. Generally, a drop in demand results in a queue that closes from the back, while an increase in bottleneck capacity results in a forward-leaning queue. The spatial extent of the queue is calculated from the number of queued vehicles and the storage space on the facility (i.e., the length and number of lanes). The temporal duration of the queue is a function of demand patterns and bottleneck capacity. The presence of a queue on a given segment also affects the rate at which vehicles can flow into the next segment. The volume arriving in downstream segments may therefore be less than the demand volume. Downstream segments with demand volumes greater than capacity may turn out to be hidden bottlenecks if a more severe upstream bottleneck meters the volume served.
- *Chapter 18, Signalized Intersections:* The cyclical maximum BOQ is computed on the basis of a queue accumulation and discharge model with a correction applied to account for acceleration and deceleration. Random arrivals and over-saturated conditions are accommodated by correction terms in the model. The computational details are provided in Chapter 31, Signalized Intersections: Supplemental. The maximum number of vehicles in the queue occurs at the end of the red phase in each cycle. The maximum BOQ extends into the subsequent green phase because vehicles continue to join the BOQ until it is fully dissipated. The measure reported for signalized approaches is the average BOQ. Percentile values are also reported.
- *Chapters 19 to 21, Unsignalized Intersections:* The 95th percentile BOQ is computed by deterministic equations as a function of demand volume, capacity, and analysis period length.

AR0073985

Stop-Related Measures

Stop-related measures are of interest to analysts because of their comfort, convenience, cost, and safety implications. An estimate of the number of stops on a signalized approach is reported by the signalized intersection analysis procedure described in Chapter 18, with details given in Chapter 31. Chapter 17, Urban Street Segments, incorporates the stops at the signal into a "stops per miles" rate for each segment. Other chapters do not report the number of stops. Most alternative tools based on both deterministic and simulation models produce an estimate of the number of stops for a variety of system elements by using the tools' own definitions, and most tools allow user-specified values for the parameters that define when a vehicle is stopped.

The Chapter 18 procedure defines a "partial" stop as one in which a vehicle slows as it approaches the BOQ but does not come to a full stop. Some alternative tools, both deterministic and simulation based, consider a partial stop to be a later stop after the first full stop.

Delay-Related Measures

The definition and computation of delay vary widely among tools.

Because of multiple definitions and thresholds, delay is one of the most difficult measures to compare among traffic analysis tools. Delay measures are reported by the same chapters in this manual that report queue measures:

- *Chapter 10, Freeway Facilities:* Delay on a freeway facility that is globally undersaturated is calculated from the sum of the delay on all individual segments. The segment delays are calculated from the travel time difference between the segment at free-flow speed and the segment at the calculated operational space mean speed. For undersaturated flow conditions, the segment space mean speed is calculated from the segment-type specific methodologies in Chapters 11 to 13. For oversaturated flow, the segment speed is estimated from the prevailing density on the segment. The travel time difference is multiplied by the number of vehicles in a segment during each time period to obtain the total vehicle hours of delay per segment and per time period. The total vehicle hours of delay on the facility for each time period and for the entire analysis are obtained by summation.
- *Chapter 18, Signalized Intersections:* The LOS estimation is based on control delay. Control delay is computed on the basis of an incremental queue analysis technique by using a queue accumulation and discharge model. Random arrivals and oversaturated conditions are accommodated by correction terms in the model. A separate correction is applied to account for an initial queue left from a previous interval. The details of the computation are provided in Chapter 31, Signalized Intersections: Supplemental.
- *Chapters 19 to 21, Unsignalized Intersections:* The LOS estimation is based on control delay. The control delay is computed by deterministic equations as a function of demand volume, capacity, and analysis period length. The LOS thresholds for unsignalized intersections are different from those for signalized intersections.

AR0073986

Density-Related Measures

Density is expressed in terms of vehicles per mile per lane and is generally recognized as an unambiguous indicator of congestion. Density is used as the determinant of LOS A through F for freeway and multilane highway segments. It is conceptually easy to define and estimate, but the question is how to apply density to the right section of roadway over the right period of time.

The procedures for different types of freeway segments follow a density estimation process that is specific to each segment type:

- *Chapter 10, Freeway Facilities*, determines density for undersaturated conditions by applying the procedures given in Chapters 11 to 13. When queuing occurs as a result of oversaturation caused by excessive demand or by bottlenecks, the density is determined by the queue-tracking procedures described previously for freeway facilities.
- *Chapter 11, Basic Freeway Segments*, determines speeds and demand flow rates that are adjusted for a variety of geometric and operational conditions. The segment density is computed by dividing the adjusted flow rate by the estimated speed. Empirical relationships are used throughout the chapter for computations and adjustments.
- *Chapter 12, Freeway Weaving Segments*, also determines density by dividing the adjusted demand flow rate by the estimated speed. The speed estimation process was described previously.
- *Chapter 13, Freeway Merge and Diverge Segments*, bases the LOS assessment on the density in the two lanes adjacent to the ramp lanes. The density is estimated directly by using empirically derived relationships that depend on the ramp and freeway (Lanes 1 and 2) volumes and the length of the acceleration or deceleration lane. Several operational and geometric factors affect the computations.

USE OF VEHICLE TRAJECTORY ANALYSIS IN COMPARING PERFORMANCE MEASURES

This section explores the use of vehicle trajectory analysis to define and estimate consistent performance measures. It first introduces the mathematical properties of trajectories as an extension of the visual properties. It identifies the types of analyses that can be performed and provides examples that illustrate how trajectory analysis can be applied. A later section identifies the performance measures that can be computed from individual vehicle trajectories and explores their compatibility with the performance measures estimated by the HCM's computational procedures. Specific trajectory analysis procedures by which consistent performance measures can be estimated are presented in Chapter 24, Concepts, Supplemental.

The concept of individual vehicle trajectory analysis was introduced in Chapter 4, Traffic Flow and Capacity Concepts. The chapter indicated that a growing school of thought suggests that a comparison of results between traffic analysis tools and methods is possible only through an analysis of vehicle trajectories as the "lowest common denominator." Trajectory-based performance measures can be made consistent with HCM definitions, with field measurement

AR0073987

techniques, and with each other. Examples of vehicle trajectory plots were shown in Chapter 4 to illustrate the visual properties of vehicle trajectories.

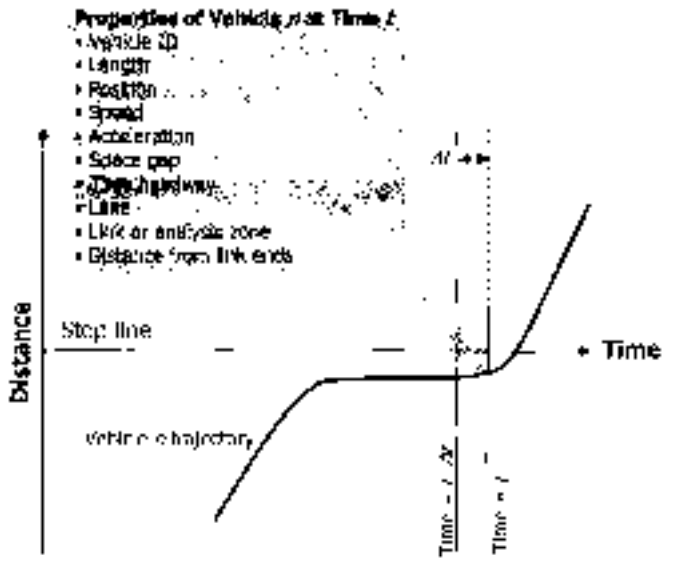
Mathematical Properties of Vehicle Trajectory

While the trajectory plots presented in Chapter 4 provide a good visual insight into operations, they do not support any quantitative assessments. To develop performance measures from vehicle trajectories, it is necessary to represent them mathematically and not just visually. A mathematical representation requires developing a set of properties that are associated with each vehicle at specific points in time and space.

Exhibit 7-5 shows the trajectory of a single vehicle through a signal. At each point in time, a number of properties may be determined. The trajectory for the vehicle is quantified through a list of the properties of vehicle *i* at each point in time. One important parameter in the quantification of trajectories is the time increment between sampling points, represented in Exhibit 7-5 as Δt. Time increments in typical simulation tools currently range from 0.1 to 1.0 s. Smaller values are gaining acceptance within the simulation modeling community because of their ability to represent traffic flow with greater fidelity.

Many properties can be associated with a specific vehicle at a point in time. Some properties are required for the accurate determination of performance measures from trajectories. Others are used for different purposes such as safety analysis. The important properties for estimating consistent performance measures are indicated in Exhibit 7-5.

Exhibit 7-5
Mathematical Properties of Vehicle Trajectories



Longitudinal and Spatial Analysis

It is necessary at the outset to distinguish between longitudinal and spatial analysis of vehicle trajectories. Longitudinal analysis involves following the presence of vehicles as they traverse a segment. The measures determined by this type of analysis include delay related measures or various types and stop-related

AR0073988

measures. Driver comfort and safety measures may also be determined by longitudinal analyses, but these measures are beyond the scope of the HCM.

Spatial analysis, on the other hand, involves considering all the vehicles on a segment at a specific time step. The two principal spatial measures include density and queue lengths. Both types of analyses are examined here.

Limitations of Vehicle Trajectory Analysis

The procedures described here and in Chapter 24 are intended to produce performance measures from vehicle trajectories that are based on the definitions of traffic parameters given in this manual to promote uniformity of reporting among different simulation tools. The results should improve the acceptance of simulation tools for highway capacity and LOS analysis. However, the term "HCM compatible" does not suggest that the numerical values of measures produced by a simulation tool will be identical to those from the HCM or to those from other simulation tools. Several factors must be considered.

Traffic Modeling Differences

The trajectory information is produced by the simulation model. Each simulation tool has its own models of driver behavior that differ from those used by other tools. It is not practical or desirable to prescribe simulation modeling details in this document. Developers continually strive to improve the realism of their products to gain a competitive advantage in the market. The Next Generation Simulation Program (13) has had some success in developing core algorithms to be shared by simulation developers, but the notion of a universal simulation model is not a practical objective.

Approximations in Trajectory Analysis

It was pointed out in Chapter 4 that all performance measures reported by deterministic models, simulation models, and field observations represent an approximate assessment of field conditions. The need for approximations in trajectory analysis to promote uniform reporting is explored in more detail in Chapter 24. One problem is that the procedures presented in this manual introduce approximations that cannot be replicated in simulation because of conceptual differences and model structure.

Differences That Are Unrelated to Trajectory Analysis

The use of vehicle trajectories addresses some, but not all, of the sources of difference in the definition of performance measures. For example, the temporal and spatial boundaries of an analysis tend to be defined differently by different tools. It is important to HCM compatibility that the definitions and guidelines presented in this manual be used in conducting simulation analyses.

Examples of Vehicle Trajectory Data

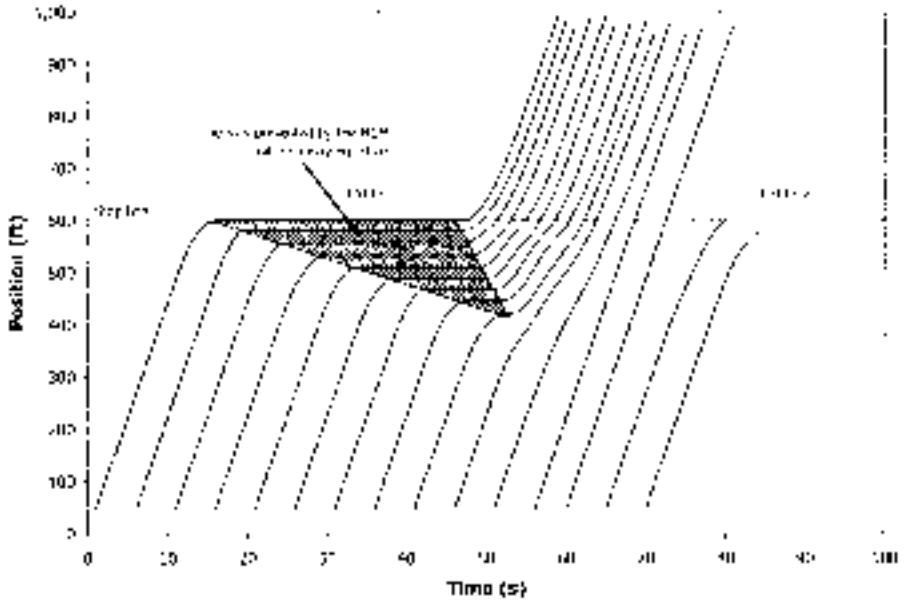
Simulation tools propagate vehicles through a roadway segment by periodically updating and keeping track of the trajectory properties that are maintained internally within the traffic flow model. Several examples of the analysis of vehicle trajectories for both interrupted- and uninterrupted-flow

AR0073989

facilities are provided in Chapter 24. The examples demonstrate the complexities that can arise in certain situations, especially when demand exceeds capacity.

Two examples are cited in Chapter 24 are presented here to illustrate how vehicle trajectories can be obtained from simulation tools. The first is shown in Exhibit 7-6, which presents the simplest possible case, involving an approach with only one lane. The simulation parameters were constrained to remove all randomness in the arrival and departure characteristics. While this situation might appear to be somewhat trivial, it is the basis of the signalized intersection delay analysis procedure summarized in Chapter 18 and described in more detail in Chapter 31.

Exhibit 7-6
Trajectory Plot for Uniform Arrivals and Departures



The trajectories may be analyzed longitudinally to produce estimates of delays and stops. They may also be analyzed spatially to produce instantaneous queue length estimates.

A more complex situation is depicted in Exhibit 7-7, which illustrates the vehicle trajectories associated with queue backup from a downstream signal. The randomness of arrivals and departures was restored to this case.

The important difference from the simple case presented in Exhibit 7-6 is that backup into a specific segment from a downstream segment is not covered by the signalized intersection analysis procedures in Chapters 18 and 31. The performance measures may be estimated by trajectory analysis. The purpose of the procedures described in Chapter 24 is to promote definitions and computational algorithms that can be made consistent among different simulation tools.

AR0073990

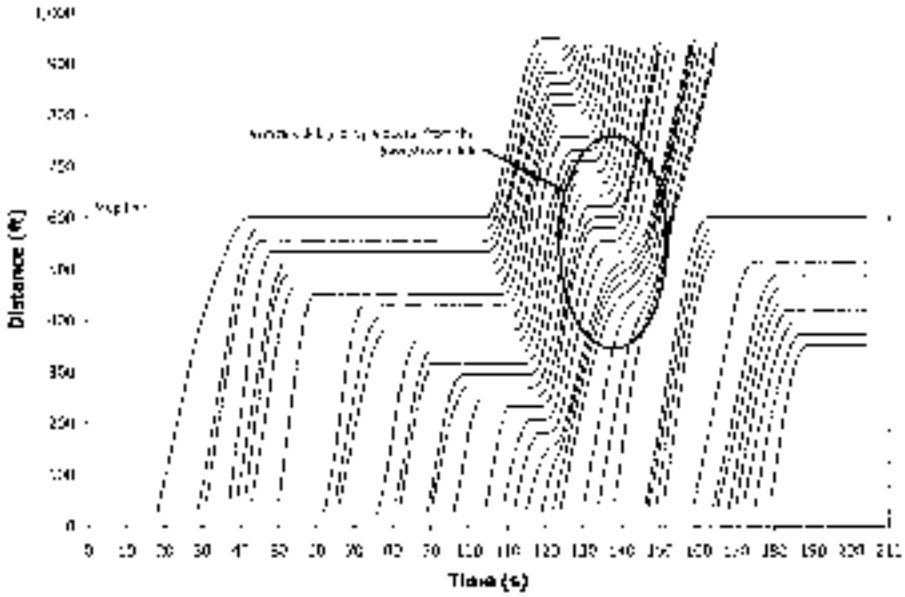


Exhibit 7-7
Queue Backup from a Downstream Signal

REQUIREMENTS FOR COMPUTING PERFORMANCE MEASURES BY VEHICLE TRAJECTORY ANALYSIS

Most performance measures reported by the procedures in this manual are also reported by simulation tools. This section identifies the general requirements for computing measures from simulation by using individual vehicle trajectories to achieve comparability between traffic analysis tools. More detailed procedures are presented in Chapter 24.

General Trajectory Analysis Guidelines

The following general guidelines apply to trajectory analysis procedures.

1. The trajectory analysis procedures are limited to the analysis of trajectories produced by the traffic flow model of each simulation tool. The nature of the procedures does not suggest the need for developers to change their driver behavior or traffic flow modeling logic.
2. If the procedures for estimating a particular measure cannot be satisfactorily defined to permit a valid comparison between the HCM and other modeling approaches, then such comparisons should not be made.
3. All performance measures that accrue over time and space shall be assigned to the link and time interval in which they occur. Subtle complexities make it impractical to do otherwise. For example, the root cause of a specific delay might not be within the link or the immediate downstream link. In fact, the delay might be secondary to a problem at some distant location in the network and in a different time interval.
4. The analyst must understand that the spatial and temporal boundaries of the analysis domain must include a period that is free of congestion on all sides. This principle is also stated in Chapter 10 for analyses of freeway facilities and in Chapter 18 for multiperiod signalized intersection analyses. To ensure that delays to vehicles that are denied entry to the

AR0073991

system during a given period are properly recognized, it might be necessary to create fictitious links outside of the physical network to hold such vehicles. A more detailed discussion of spatial and temporal boundaries is provided later in this chapter.

5. It is important to ensure that the network has been properly initialized or "seeded" before trajectory analysis is performed. When setting and applying the warm-up periods, simulation tools typically start with an empty network and introduce vehicles until the vehicular content of the network stabilizes. Trajectory analysis should not begin until stability has been achieved. If the simulation period begins with oversaturated conditions, stability may never be achieved. See the discussion later in this chapter on temporal and spatial boundaries.

Speed- and Travel Time–Related Measures

Speed and travel time are treated together because, at least for segment values, they are closely related. The average speed of a vehicle traversing a segment may be determined by dividing the segment length by the travel time.

Macroscopic segment travel time estimation does not require a detailed trajectory analysis. The travel time for an individual vehicle may be computed for a given segment by subtracting the time when the vehicle entered the segment from the time when it left the segment. The average travel time may be computed as the mean of the individual travel times; however, this technique is valid only for complete trips (i.e., those that have entered and left the segment).

The space-mean speed for all vehicles within the segment during the time period may be estimated by dividing the number of vehicle miles of travel by the number of vehicle hours of travel time. The total vehicle miles and vehicle hours may be accumulated by including all the vehicles and time steps in the analysis domain. See the discussion later in this chapter on spatial and temporal boundaries.

Queue-Related Measures

Because of their microscopic nature, simulation tools have the potential to produce useful measures of queuing that are beyond the limits of those described in the procedural chapters of this manual. However, the queue-related performance measures are difficult to compare with those derived from HCM procedures. No such comparisons should be attempted without a detailed knowledge of the queue definitions and computations of a specific tool. With consistent definitions, more uniform queue measures could be obtained from simulation tools.

Queued State

What defines the entry to and exit from a queue? Several definitions are applied by different tools for this purpose. The definition given in Chapter 31 for purposes of field observations states the following.

> *A vehicle is considered as having joined the queue when it approaches within one car length of a stopped vehicle and is itself about to stop. This definition is*

AR0073992

and because of the difficulty of keeping precise track of the moment when a vehicle comes to a stop.

The Chapter 31 definition of the exit from a queue, also intended for application to field studies, is more complex and offers some interesting challenges for implementation in both deterministic and simulation models. As a practical approximation, a vehicle should be considered to have left the queue when it has left the link on which it entered the queue. When a queue extends the full length of a link, a vehicle should be considered to enter the queue at the time it enters the link. Other conditions, such as a lane change to escape a queue, might also signal the exit from a queue. These conditions are discussed in Chapter 24.

Queue Length

The estimation of queue length is generally required to determine whether a queue has reached the point where it will interfere with other traffic movements. Queue length computations are applied at a macroscopic level by the procedures described in this manual. Simulation models, on the other hand, are able to establish the instantaneous BOQ at each point in time. The question is how to process the instantaneous values in a manner that will produce meaningful results.

Queue length analysis by simulation must be treated differently for different conditions. There are three cases to consider:

1. *Undersaturated noncyclical operation*, typical of the operation with isolated two-way stop control. In this case, the queue accumulation and discharge follow a more or less random pattern. The Chapter 19 procedure estimates the 95th percentile queue length on the basis of a deterministic average queue length modified by a term that accounts for random arrivals. This process could be approximated in trajectory analysis by establishing a distribution of instantaneous queue lengths by time step. The 95th percentile queue length could be determined from that distribution.
2. *Undersaturated cyclical operation*, typical of the operation at a traffic signal. In this case, a maximum BOQ is associated with each cycle. The maximum BOQ in each cycle represents one observation for statistical analysis purposes. The use of a distribution of instantaneous values is not appropriate here because the queue accumulation and discharge are much more systematic than random. Including instantaneous queue lengths that occur when the queue is expected to be zero (i.e., at the end of the green) would underestimate the measure of interest, which is the peak queue length. With a sufficient number of cycles, a distribution of peak queue lengths with a mean value and a standard deviation could be established. The probability of queue backup to any point could then be estimated from this distribution.
3. *Oversaturated operation*, either cyclical or noncyclical: When demand exceeds the capacity of an approach or system element, the queue will grow indefinitely. For purposes of simulation, the measure of interest is

AR0073993

the residual RQ at the end of the simulated interval and the effect of the queue on upstream segments. These considerations are especially important in multiperiod analyses.

The undersaturated condition might include brief periods of queue buildup and discharge as long as continuous buildup and residual queues do not occur.

Stop-Related Measures

Most alternative tools based on both deterministic and simulation models produce an estimate of the number of stops by their own definition, and most allow user-specified values for the parameters that establish the beginning and end of a stop. Stop-related measures are of interest in analysis because of their comfort, convenience, cost, and safety implications.

Definition of the Stopped State

The definition of when a vehicle is stopped has the same two elements as the definition of when it is queued—that is, when does the stop begin and when does it end? Speed thresholds are often used to determine when a vehicle is stopped. The only nonarbitrary threshold for this purpose is zero. Practical considerations suggest, however, that simulation modeling algorithms that deal with stopping would be more stable if a near-zero speed were used instead. A speed of 5 mi/h was applied in other chapters for determining when a vehicle has stopped.

There are two different modeling purposes for releasing a vehicle from the stopped state:

- To terminate the accumulation of stopped delay, and
- To enable the accumulation of subsequent stops.

The first condition is easier to deal with in the trajectory analysis. When the vehicle is no longer stopped, it should no longer accumulate stopped delay. The logical speed threshold for this condition is the same speed threshold that established the beginning of the stop.

Estimating the Number of Stops

The accumulation of multiple stops poses more problems and generally relies on arbitrary thresholds that vary among different tools. The main problem with multiple stops is that, after the first stop, later stops take place from a lower speed and therefore have a less adverse effect on driver comfort, operating costs, and safety. For signalized approaches, some tools apply a "probability of stopping" model in which the maximum probability is 100% and, therefore, the maximum number of stops is 1.0 on any approach. Other tools model subsequent stops based on the release from the stopped state when the vehicle reaches an arbitrary threshold speed, often around 15 mi/h.

While the number of stops is an important performance measure, it is difficult to compare the values produced by different tools. Such comparisons should not be attempted without adequate knowledge of the definitions and parameters that are used by a specific tool.

AR0073994

Delay-Related Measures

Practically all traffic analysis tools produce a performance measure called "delay," but tools vary widely in the definition and computation of delay. This discussion attempts to establish consistent definitions for delay.

Delay Definitions

Delay is generally defined as the excess time spent on a road segment compared with the time at a target speed that represents a zero-delay condition. The target speed is the speed at which a specific driver prefers to drive. Different tools have different definitions of target speed. Some are driver and vehicle specific, taking into account driver aggressiveness and roadway characteristics. Because target speed is a function of individual driver behavior, there will be some differences in the method of computation, especially if the target speed is different for each vehicle. For tools that require a user-specified free-flow speed as an input, the methodology presented in the procedural chapters of this manual should be used to determine the free-flow speed.

The time a vehicle actually spends on a segment is easy to determine from its trajectory. On the other hand, the target time is subject to a number of definitions.

- *Travel time at ideal speed*, usually the free-flow speed.
- *Travel time at the individual vehicle's target speed*: a function of the free-flow speed, prevailing roadway and traffic conditions, and the driver's characteristics.
- *Travel time at 10 mi/h below speed limit*: used by some agencies to determine whether a trip is "on time" for travel time reliability reporting. This measure defines "extreme delay."
- *Travel time at a specified travel time index*: The travel time index is the ratio of actual travel time to ideal travel time. It is used primarily for reporting congestion in nationwide mobility monitoring. A travel time index of 1.5 is sometimes taken as an indication of congestion. This measure defines congestion delay. It is intended to be an indicator of the need for roadway improvements.
- *Travel time without traffic control*: This measure defines control delay. Unlike the previous measures, which are applied to an entire segment, control delay is applied only to the portion of the segment where a queue is present. Control delay is a subset of segment delay because it does not include the delays caused by traffic interactions upstream of the queue. The definition applies uniformly to all types of control, including signals, stop signs, and roundabouts.

In all cases, a lower limit of zero must be imposed when the actual travel time is shorter than the reference time.

Aggregated Delay Versus Unit Delay

It is important to note the difference between aggregated delay, usually expressed in vehicle hours, and unit delay, usually expressed in seconds per

AR0073995

vehicle. Aggregate delay is generally used to assess the operating costs associated with a candidate treatment, because an economic value can be assigned to a vehicle's hour of delay. Unit delays are associated with driver perception of the LOS on a facility. For these two definitions to be dimensionally consistent, the unit delays must actually be expressed in vehicle seconds per vehicle. It is common practice, however, to shorten the definition to seconds per vehicle to promote public understanding.

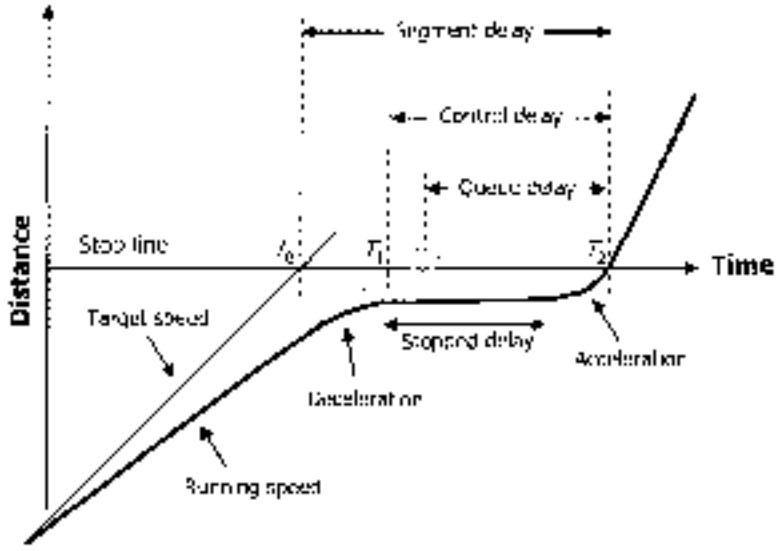
Representation of Delay by Vehicle Trajectories

Several delay definitions were presented previously. These definitions may be interpreted in terms of vehicle trajectories based on longitudinal trajectory analysis. In all cases, the delay is determined for each time step and accumulated over the entire time the vehicle was in a specified segment.

Exhibit 7-8 illustrates the various ways delay may be defined. These points are entered in this figure.

- T_A, the time at which a vehicle would have arrived at the stop line if it had been traveling at the target speed;
- T_t, the time at which a vehicle would have arrived at the stop line if it had been traveling at the running speed, which is generally less than the target speed because of traffic interactions; and
- T_D, the time at which a vehicle is discharged at the stop line.

Exhibit 7-8
Definition of Delay Terms in Time and Space



The delay measures defined in terms of the time differences shown in Exhibit 7-8 include the following.

- Control delay, defined as $T_D - T_t$. This delay definition is the one used by the procedure for assessing LOS at control-type intersections and roundabouts.

AR0073996

- *Segment delay*, defined as $T_2 - T_1$. This definition is more commonly used by simulation tools. It reflects the delay experienced by each vehicle since it left the upstream node (usually another signal). Segment delay includes control delay plus all other delay due to traffic interactions.

In addition to these two precisely defined delay terms, two other delay definitions are shown in Exhibit 7-8 that are based on more complex properties of the vehicle trajectories:

- *Stopped delay*, which reflects the amount of time a vehicle was actually stopped. The beginning and end of a stop are generally based on speed thresholds, which may differ among tools. In some cases, the threshold speeds are user definable.
- *Queue delay*, which reflects the amount of time a vehicle spends in a queued state. The properties of the trajectory that define a queued state in different tools include speed, acceleration, spacing, and number of vehicles sharing these properties. For trajectory analysis purposes, the queued state was defined previously in this chapter, and this definition is reflected in Exhibit 7-8.

For simulation tools that report total segment delay but do not report control delay explicitly, it is possible to produce approximate estimates of control delay by performing simulation runs with and without the control device(s) in place. The segment delay reported with no control is the delay due to geometrics and interaction between vehicles. The additional delay reported in the run with the control in place is, by definition, the control delay. For short segments with low to medium volumes, the segment delay usually serves as an approximation of the control delay.

The development of control delay estimates by a multiple-run procedure is primarily of academic interest because of the amount of effort involved. The objective at this point is to develop a specification for estimating control delay from vehicle trajectories that may be intermalized by simulation model developers to produce HCM-compatible results.

Computational Procedures for Delay-Related Measures

The procedures for computing delay from vehicle trajectories involve aggregating all delay measures over each time step. Therefore, the results take the form of aggregated delay and per unit delay, as defined earlier. To determine unit delays, the aggregated delays must be divided by the number of vehicles involved in the aggregation. Partial trips made over a segment during the time period add some complexity to unit delay computations.

The following procedures should be used to compute delay-related measures from vehicle trajectories:

- *Time step delay*. The delay on any time step is, by definition, the length of the time step minus the time it would have taken the vehicle to cover the distance traveled in the step at the target speed. This value is easily determined and is the basis for the remainder of the delay computations.

AR0073997

- *Segment delay.* Segment delay is represented by the time taken to traverse a segment minus the time it would have taken to traverse the segment at the target speed. The segment delay on any step is equal to the time step delay. Segment delays accumulated over all time steps in which a vehicle is present on the segment represent the segment delay for that vehicle.
- *Queue delay.* The queue delay is equal to the time step delay on any step in which the vehicle is in a queued state; otherwise, it is zero. Queue delays are accumulated over all time steps while the vehicle is in a queue.
- *Stopped delay.* The stopped delay is equal to the time step delay on any step in which the vehicle is in a stopped state; otherwise, it is zero. Since a vehicle is considered to be stopped if it is traveling at less than a threshold speed, a consistent definition of stopped delay requires that the travel time at the target speed be subtracted. Time step delays accumulated over all time steps in which the vehicle was in the stopped state represent the stopped delay. Earlier versions of this manual defined stopped delay as 90% of the control delay, on the basis of empirical data.

Queue delay computed from trajectory analysis provides the most appropriate representation of control delay.

- *Control delay.* Control delay is the additional travel time caused by operation of a traffic control device. The queue delay computed from vehicle trajectories provides a reasonable approximation of control delay when the following conditions are met:
  1. Queue delay is caused by a traffic control device, and
  2. Identification of the queued state is consistent with the definitions provided in the HCM.

Special Delay Estimation Issues

It is not possible to compute control delay from individual vehicle trajectory analysis in a manner consistent with the procedures in this manual that report control delay. It was demonstrated earlier in this chapter (see Exhibit 7-6) that the uniform delay term d_1 described in Chapter 18 is derived from trajectory analysis. The problem is that the delay adjustment terms d_2 and d_3 are macroscopic observations that have been derived analytically. As such, they cannot be represented by vehicle trajectories. When demand volumes approach and exceed capacity, the correction terms become very large.

Exhibit 7-8 showed the trajectory of a single vehicle in an undersaturated situation. From this figure, it is observed that the control delay will be the same as the queue delay when their travel times projected to the stop line at the running speed (i.e., the broken lines) follow the same path. The problem is that the additional delays from the d_2 and d_3 adjustment terms are not represented in the figure. The adjustment terms are represented implicitly in the queue delays produced by trajectory analysis. As such, they remain a valid estimator of control delay at all levels of saturation.

While the queue delay from trajectory analysis generally provides a reasonable estimate of the delay on a controlled link, it is important to recognize certain phenomena that raise interpretation issues. The first is geometric delay, which is not included in the Chapter 18 procedure. For example, a large truck

AR0073998

turning right can cause additional delay to vehicles in a queue behind it. The additional delay, which would be ignored by the Chapter 18 control delay calculations, would be interpreted by trajectory analysis as control delay. This situation would cause problems in comparing the control delay estimates from the two methods.

Another problem arises with oversaturated conditions. The conceptual differences between the analytical delay model of Chapter 18 and the microscopic simulation approach make it difficult to compare their results. The comparison becomes even more complicated when queues extend into upstream links.

Density-Related Measures

Density is one of the easiest measures to compute from vehicle trajectories because it involves simply counting the vehicles in a section of roadway at a specific time. Density is therefore a product of spatial analysis as opposed to longitudinal analysis. The question is how to apply the proper definition of density to the right section of roadway over the right period of time. For example, a main obstacle in comparing densities reported by the procedural chapters in this manual with those reported by simulation tools is that different definitions. The procedures in this manual report density in terms of passenger cars per mile. Simulation tools report this measure in terms of actual vehicles per mile. The simulated densities must be converted to passenger cars per mile to produce comparable results. Procedures for conversion are discussed in Chapter 24, Concepts: Supplemental.

Because of the importance of density as a determinant of LOS, it is desirable to establish trajectory analysis procedures that are compatible with the HCM so that simulated densities can be used for LOS estimation. Microscopic simulation models establish the position of all vehicles in the system at all points in time, making it easy to define and compute density measures that are uniform among different tools by simply counting the number of vehicles on a specified part of a roadway.

Computational Procedures

The equivalent density at a point can be determined by simulation by using a simple equation that relates density to the spacing of vehicles:

$$\text{Density (veh/mi)} = \frac{5{,}280 \text{ ft/mi}}{\text{Vehicle spacing (ft/veh)}} \qquad \text{Equation 7-1}$$

Density can also be computed macroscopically at the segment level by simply counting the number of vehicles present on the segment during a particular time step. The density by time step may be aggregated over an analysis period by computing the arithmetic mean of the time step densities. This method of measurement and aggregation should produce density values that are compatible with the HCM in both definition and computation, provided that the demand (v) does not exceed the capacity (c). For v/c ratios greater than 1.0, the density at the end of the analysis period may be of more interest than the average density.

AR0073999

Density is computed on a per lane basis in the examples given in Chapter 24. The combined density for the ramp influence area (the two freeway lanes adjacent to the ramp plus auxiliary lanes, if any, within 1,500 ft of the ramp junction) is also computed because of its application to freeway merge and diverge ramp functions. To compute the average density for a series of segments in a freeway facility, the procedure outlined in Chapter 10 should be used.

Follower Density

This measure is derived in terms of the number of followers per mile on a two-lane highway. Follower density is not reported in this manual. Instead, percent time spent following is used as a determinant of LOS for two-lane highways in Chapter 15. The definition of the following state is given in Chapter 15 as a condition in which a vehicle is following its leader by no more than 3 s. The concept of follower density has attracted increasing international interest. It is a measure that could be easily derived from a typical analysis.

STOCHASTIC ASPECTS OF SIMULATION ANALYSIS

Two HCM's deterministic procedures give a unique result for a given set of inputs, while stochastic tools may give a distribution of results for a given set of inputs over a series of runs.

The deterministic procedures in the HCM give a unique value for all performance measures based on the specifics of the input data. Stochastic analysis tools apply a randomization process that might give different values for performance measures each time the process is repeated. In other words, simulation tools produce a distribution of values for each performance measure, much as would be expected from a series of repeated field studies. It is essential in supporting decision making to represent the distribution of values in terms of a single representative value.

A comprehensive tutorial on the stochastic aspects of simulation is presented elsewhere (14). Topics covered include confidence intervals, the number of runs required to achieve a specified level of confidence, and hypothesis testing for comparing alternative configurations and strategies. The tutorial material is not repeated here, but it should be understood by analysts who are using simulation to produce performance measures that are comparable with those described in this manual.

Simulation modeling is based on internally generated random numbers that are controlled by specifying an initial random number or "seed" to start the generation process. In some cases, multiple seeds are used to control different aspects of the randomization. For example, driver characteristics and vehicle characteristics might be seeded differently. Multiple runs using a simulation tool with the same input data and random number seed(s) will produce the same answers. To establish a range of answers, repetitions must be created by running a simulation tool with the same input data with different random number seed(s). Most simulation tools provide guidance on selecting random number seeds.

Number of Required Repetitions

The result of a set of simulation runs is normally represented by a summary of the average values of the performance measures of interest. Confidence in the results is influenced by the number of runs included in the set. The question

AR0074000

raised here is "How many runs are needed?" The answer depends on three parameters:

1. The maximum error that can be tolerated in the results. The tolerable error may be expressed in terms of an absolute value (e.g., 5 s of delay) or as a percentage of deviation from the true mean value. Greater acceptable maximum error (tolerance) suggests the need for fewer runs.
2. The degree of confidence that the true mean falls within the specified error limits. A greater degree of confidence (i.e., 99% as opposed to 95%) suggests a need for more runs.
3. The variability across simulation runs given by the standard deviation. A greater variability (higher standard deviation) suggests a need for more runs, if the other two parameters stay fixed.

In accordance with a basic statistical approach, the standard error of the mean may be estimated from the simple relationship in Equation 7-3:

$$E = \frac{s}{\sqrt{n}} \qquad \text{Equation 7-2}$$

where

E = standard error of the mean,

s = standard deviation of the set of runs for a particular performance measure, and

n = number of runs included in the set.

The confidence limits are expressed in terms of the number of standard errors from the mean value. A target of 95% confidence is often used for this purpose. The 95% confidence interval is represented by the mean value ±1.96 standard errors.

From the above relationship, it is possible, given the sample standard deviation s, to calculate the required sample size to produce 95% confidence of achieving a maximum tolerable error E_t by using Equation 7-3:

$$n = (1.96s)^2 / (E_t)^2 \qquad \text{Equation 7-3}$$

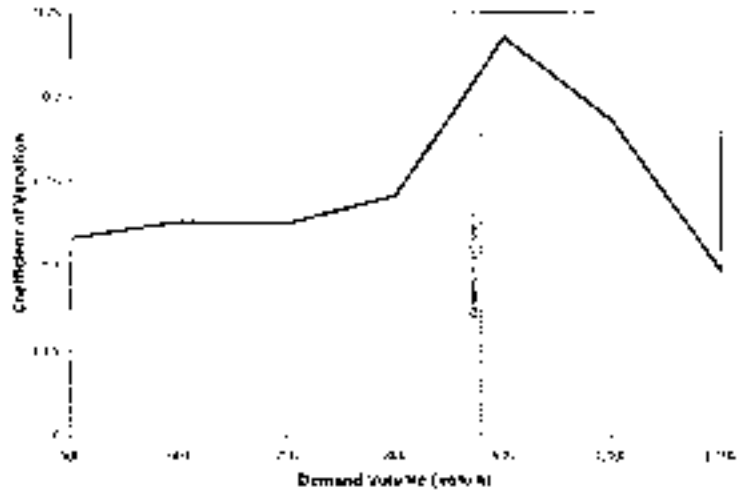
A few statistically oriented sites on the Internet offer online calculators for determining required sample sizes.

Expected Variation Between Runs

It is difficult to anticipate the amount of variation that will result from a set of runs given the input data. The standard deviation of a given performance measure is best determined by making a set of test runs and applying the sample size calculations. One factor that influences the variability of signalized intersections is the degree of saturation on each approach. This influence is illustrated in Exhibit 7-5, which shows the coefficient of variation (standard deviation/mean) on a simple signalized approach as a function of the approach volume. The data for this example included 30 runs for a 15-min period.

AR0074001

Exhibit 7-9
Effect of Demand Volume on Variability of Simulated Delay on an Approach to a Signalized Intersection



At low volumes, the variability is low, with the standard deviations approaching 10% of the mean value. The variability peaks at the capacity of the approach at a value near 25%. The variability is highest at capacity because some runs will see more undersaturated cycles in the operation, while others will see more oversaturated cycles. As demand volume increases well beyond approach capacity, the variability decreases significantly as deterministic phenomena begin to govern the operation.

Exhibit 7-9 shows the relationship for a single approach to an intersection. Variability may also be expected to decrease in larger systems, as illustrated in Exhibit 7-10. This example shows a very large system with 472 links, obtained from the sample data distributed with one simulation tool. The data set included 20 runs covering a 15 min period. The performance measures cover the entire system, and the resulting variation is substantially lower than would be expected on a single approach.

Exhibit 7-10
Variability of Overall Performance Measures for a Large Urban Network

Statistic	Vehicle Miles Traveled	Vehicle Hours Delay	Vehicle Hours Total	Minutes per Mile Delay	Minutes per Mile Total	Average Speed (Mi/h)
Mean	19,467	738	761	0.731	2.347	25.571
Standard deviation	140	7	9	0.019	0.021	0.213
CV	0.007	0.009	0.012	0.026	0.009	0.008
Standard error	31	1.49	1.96	0.00	0.00	0.05
Upper 95%	19,579	748.497	765.197	0.747	2.356	25.667
Lower 95%	19,496	234.661	757.508	0.725	2.337	25.475

Note: CV = coefficient of variation.

AR0074002

COMPARING HCM ANALYSIS RESULTS WITH ALTERNATIVE TOOLS

At the start, it must be recognized that alternative traffic analysis tools have been used for many years and that not all their applications have a strong requirement for HCM compatibility. The guidance presented in this chapter and in the procedural chapters of Volumes 2 and 3 is addressed specifically to analysts who are seeking some degree of compatibility with the HCM procedures through the use of alternative tools. It is not the intent of the HCM to duplicate the tutorials and other authoritative documents in the literature dealing with the general application of traffic analysis tools.

Full numerical compatibility between the HCM and alternative tools is often unavoidable because of differences in defining, modeling assumptions, and computational methodologies.

Full numerical compatibility between the HCM and simulation-based analysis is seldom attainable because of differences in definitions, modeling approaches, and computational methodologies. An earlier section of this chapter dealt with the use of vehicle trajectory analysis to promote consistent definitions and computational procedures for the most important performance measures. The guidance in this section covers the following areas:

- Recognizing situations in which alternative tools should be applied,
- Recognizing situations in which basic incompatibilities preclude direct comparisons between the HCM and simulation results, and
- Achieving maximum compatibility between the HCM procedures and those of alternative tools.

Conceptual Differences Between Modeling Approaches

The analysis procedures described in this manual are based on deterministic models that are well founded in theory. They are implemented in the form of equations that describe the behavior of traffic. Most of the equations include empirical calibration factors derived from research. Simulation modeling, on the other hand, is based on the propagation of fictitious vehicles along a roadway segment in accordance with principles of physics, rules of the road, and driver behavior. While both modeling approaches attempt to replicate phenomena that can be observed and quantified in the field, it is sometimes difficult to obtain results that are mutually comparable. The conceptual differences that preclude comparison are discussed in the procedural chapters. A summary of key differences is presented here:

- Delays reported by the HCM interrupted-flow analysis procedures apply to all the vehicles that arrive during the analysis period. When demand volumes exceed capacity, the delay to vehicles entering the system during a given period and leaving during a subsequent period are excluded. Delays reported by simulation are those experienced within the analysis period regardless of when vehicles entered or left the system. This concept is explored in more detail later in this chapter in the discussion of multiperiod operation.
- Densities reported by the uninterrupted-flow chapters in terms of passenger cars per mile. Passenger car equivalency (PCE) factors are used to convert heavy vehicles to passenger cars. PCEs are applied before the density computations. Densities reported by simulation are generally expressed in actual vehicles per mile. The effect of heavy vehicles is an

AR0074003

implicit result of their different characteristics. Because of this difference, it is difficult to apply PCE factors in reverse to the results of the computations.

- The procedures in this manual deal with peak 15-min-period demand flow rates, sometimes determined by applying a PHF to hourly volumes. Simulation models do not normally apply a PHF to input volumes. Therefore, some care must be taken to ensure that the demand and time periods are represented appropriately to promote the development of comparable results.
- The procedures for analysis of urban street operations focus on performance measures for arterial through vehicles. Simulation tools generally consider all vehicles, including turning movements on a street segment. To obtain comparable results from simulation, it is necessary to isolate the through movements.
- The procedures for analysis of ramp merge and diverge segments focus on traffic density within the influence of the merge area (usually the ramp and the two adjacent lanes). To obtain comparable results from simulation, it is necessary to define the merge area as a separate segment for analysis and to isolate the movements in the adjacent lanes.
- HCM procedures typically do not consider the effect of self-aggravating phenomena on the performance of a segment. For example, when traffic in a left-turn bay spills over into the adjacent through lane, the effect on the through lane performance is not considered. The inability of drivers to access their desired lane when queues back up from a downstream facility is not taken into consideration.
- Random arrivals in the traffic stream are also treated differently by the two modeling approaches. The HCM's interrupted-flow procedures apply analytical correction factors to account for this effect, while simulation modeling treats randomness explicitly by generating vehicle arrivals from statistical distributions. The difference between the two treatments affects the comparability of results.
- Some simulation tools either require or have the option of entering the origin–destination matrix instead of link and turning movement volumes. In these cases, the link and turning movement volumes are outputs from the dynamic traffic assignment models implemented as parts of the tools. HCM procedures require the link or turning movement counts as inputs.

Framework for Comparison of Performance Measures

The application framework for alternative tools is presented in the form of a flowchart in Exhibit 7-11. This framework applies to all the procedural chapters in Volumes 2 and 3.

The first steps in this flowchart deal with identifying whether the situation will support analyses in which some degree of compatibility between the HCM and alternative tools may be achieved. If it is determined that, because of conceptual differences in definitions and modeling, no potential for comparability

AR0074004

exists, then the use of alternative tools should be limited to feasibility assessment and comparison of candidate solutions. It is anticipated that, in most cases, there will be potential areas of incompatibility.

The next steps cover the conduct of simulation analysis to achieve the desired level of compatibility with the HCM. Four steps are involved:

1. Calibrate the simulation parameters to the HCM, usually by seeking equal capacities from both processes.
2. Perform a statistically appropriate number of simulation runs.
3. Interpret the results.
4. Make iterative adjustments to calibration parameters to reconcile differences.

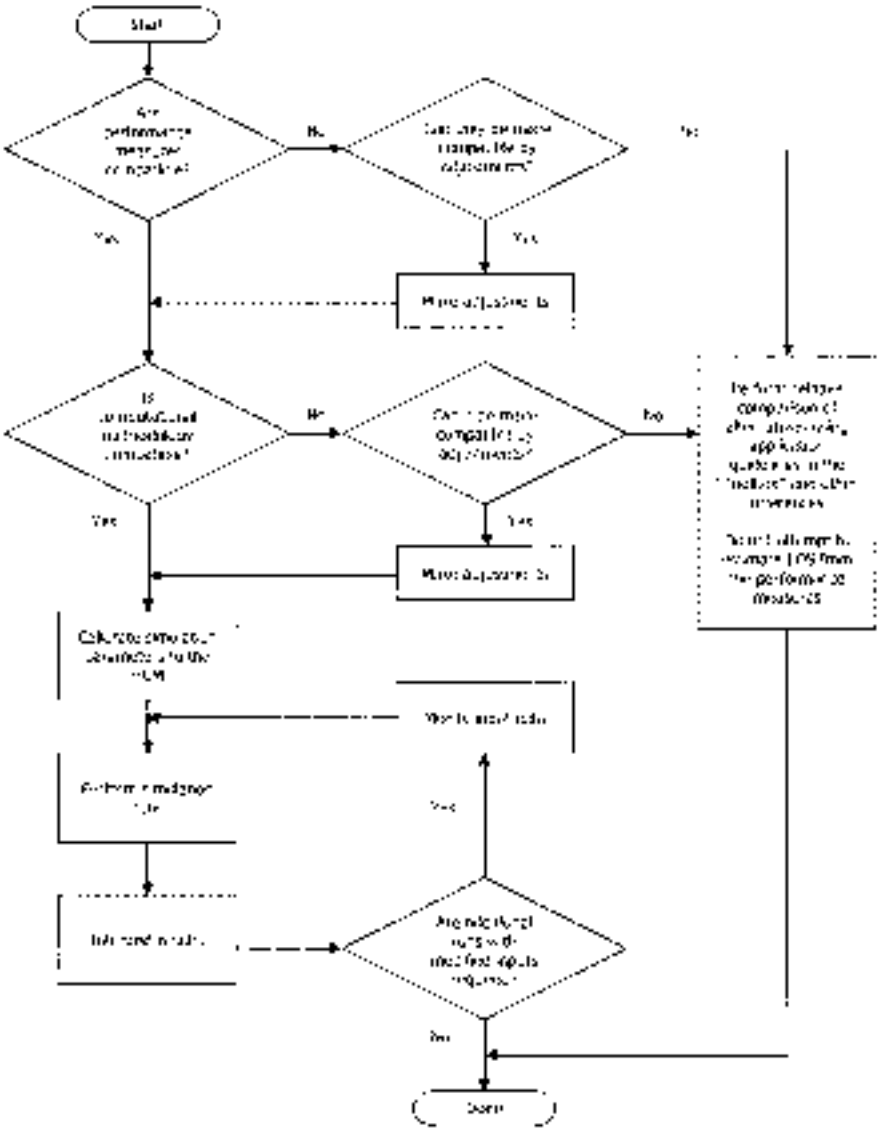


Exhibit 7-11
Application Framework for Alternative Tools

AR0074005

Alternative tools that report a performance measure with the same name as an HCM service measure, but with a different method of computation, should not be used to estimate LOS for purposes of the HCM.

LOS Comparisons

LOS estimates are determined by applying thresholds to specified performance measures (i.e., service measures). When LOS is estimated from performance measures obtained from an alternative tool, it is essential that the performance measure be determined in the same way the HCM determines the same measure. Alternative methods may be used to estimate and compare performance measures as long as they are both trying to estimate the same fundamental measurement. Alternative tools that report a performance measure with the same name as an HCM measure, but with a different method of computation, should not be used to estimate the LOS for purposes of the HCM.

At this point, simulation tools do not generally report performance measures by using the definitions and trajectory-based method of estimation suggested in this chapter and in Chapter 24. Some refinement in the alternative tool definitions and methods of estimation based on vehicle trajectory analysis is required before valid comparisons can be made. The value of simulation modeling as a useful decision support tool is recognized, but the validity of direct comparison with performance measures defined by this manual is questionable unless the definitional and computational procedures conform to those prescribed in this chapter.

HCM LOS thresholds are often based on service measures representing the peak 15 min of demand (arriving vehicles) rather than the 15-min period when the measure reached its maximum value.

It is also important to note that the HCM applies LOS thresholds to performance measures that represent the peak 15 min of demand (i.e., arriving vehicles) and not necessarily the 15-min period when the performance measure produced its maximum value.

The presence of significant queues at the end of an analysis period can often be taken as an indicator that LOS F has been reached.

One consideration that makes simulation more compatible with the HCM in reporting LOS is the criterion that, for most roadway segments, LOS F is assigned to any segment that operates above its capacity. Therefore, without the need for a detailed trajectory analysis, the presence of significant queues at the end of the analysis period can be taken as an indicator that LOS F has been reached in the segment. When queues extend into a given segment from a downstream bottleneck, it is important to use the analysis procedures for freeway facilities described in Chapter 10 of this manual instead of the procedures for individual segments described in Chapters 11 to 15. On the other hand, when the purpose of the analysis is to develop a facility design that will produce a LOS better than F, the analyst must ensure that the performance measure on which LOS is based is estimated in a manner compatible with the HCM.

Estimation of Capacity by Simulation

It is commonly accepted that the capacity of an approach or segment may be estimated by overloading it and observing the maximum throughput. This technique is valid in some cases, but it must be used with caution when congestion could become a self-aggravating phenomenon. For example, when lane selection is important (as in the case of a turning bay) and congestion keeps vehicles from their desired lane, the throughput can drop below its theoretical maximum. This phenomenon is not recognized by most of the HCM's deterministic analysis procedures. Therefore, if the objective is to seek HCM compatible capacity levels, the approach or segment should not be overloaded.

AR0074006

by more than a few percent. In this case, the process of determining capacity might require iteration. On the other hand, if the objective is to evaluate the operation under an anticipated heavy overload, then simulation modeling might provide some insight into the nature of the resulting congestion. In that case, the analysis could require development of the relationship between demand and throughput. Examples of the adverse effects of heavy overloading are presented in Chapter 27, Freeway Weaving: Supplemental, and Chapter 34, Interchange Ramp Terminals: Supplemental.

Temporal and Spatial Boundaries

The LOS reported by the HCM procedures applies to the 15-min period with the maximum number of arrivals (i.e., entering vehicles). This period might not be the same one that reports the maximum delay because of residual queues. In a discussion of the limitations of performance measure estimation and use (*15*), there is frequent reference to the issues that arise in the treatment of incomplete trips within the analysis period, including those that entered the spatial domain of the analysis but did not exit during the analysis period and those that were unable to enter the spatial domain because of queue backup. The main problem lies in differences in treatment among different modes.

Definition of incomplete trips within the temporal and spatial boundaries of an analysis

Complete Versus Incomplete Trips

Five categories are proposed with respect to incomplete trips (*15*).

1. Vehicles that were present at the start of the analysis period and were able to exit the system successfully before the end of the analysis period;
2. Vehicles that were present at the start of the analysis period but were unable to exit the system successfully before the end of the analysis period;
3. Vehicles that were able to enter the system during the analysis period but were unable to exit the system successfully before the end of the analysis period;
4. Vehicles that tried to enter the system during the analysis period but were unsuccessful; and
5. Vehicles that entered during the analysis period and were able to exit the system successfully before the end of the analysis period.

All categories except the fifth represent incomplete trips. It is suggested elsewhere (*15*) that, if a specific analysis contains more than 5% incomplete trips, the period length should be increased.

It is important to recognize that the objectives of the Federal Highway Administration's *Traffic Analysis Toolbox* (*16*) differ somewhat from those of the HCM. The purpose of the *Toolbox* is to provide general guidance on applying traffic analysis tools. The guidance on simulation included in this chapter is more focused on developing HCM-compatible performance measures so that those measures can be used in conjunction with the HCM procedures. Therefore, this discussion must examine temporal and spatial boundaries from the same perspective as the HCM procedures.

AR0074007

When oversaturated operation is being studied, the definition of the facility in time and space is much less important. The operation tends to be more homogeneous when *v*/*c* ratios are less than 1.00. Extending the analysis period will give a larger sample of vehicles for most performance measures but will not affect the measures significantly.

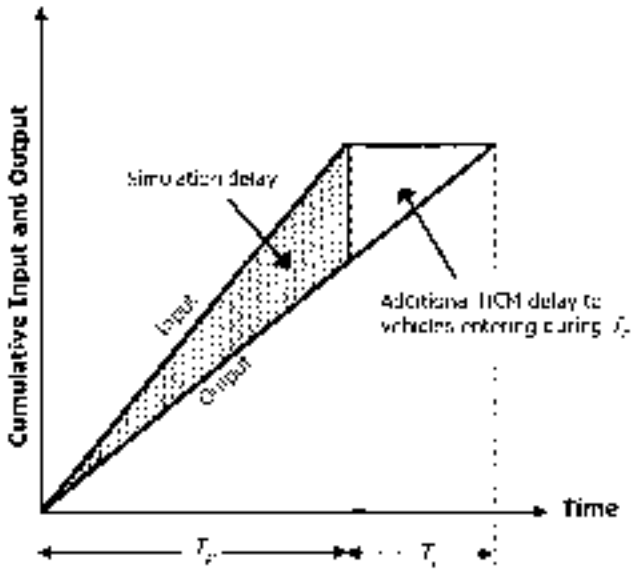
The issues are more complicated when the *v*/*c* ratio is greater than 1.00 for short periods. In this case, queues build up and the analysis (either HCM or simulation) must define temporal boundaries that begin and end without congestion. It is also desirable, but not essential, that the spatial boundaries encompass uncongested operation. Failure to define a spatially adequate system will result in vehicles being denied entry, but those vehicles will eventually be processed if the analysis period is long enough.

Delay on Oversaturated Signalized Approaches

LOS for interrupted flow is defined by the HCM in terms of the delay to all vehicles entering the facility during the analysis period. All vehicles wishing to enter are assumed to enter. Those unable to exit from a signalized intersection are accumulated in a residual queue and are assumed to exit later. The incremental (d_2) term of the delay model accounts for delay to vehicles that exit in a later period. The d_3 term accounts for the additional delay caused by an initial queue.

The formulation illustrated in Exhibit 7-12 recognizes that delay accrues when the vehicular input to a system exceeds the output for a period of time. The HCM uses this formulation to estimate delay that accrues at a signalized intersection when volume exceeds capacity over the analysis time period, T_f. The HCM delay in Exhibit 7-12 is represented by the area of the two triangles sunwen in the figure. The area within the two triangles is referred to as the deterministic queue delay (DQD). The DQD may be determined as $0.5 \times T_f \times (X - 1)$, where X is the *v*/*c* ratio.

Exhibit 7-12
Oversaturated Delay Representation by the HCM and Simulation Modeling



AR0074008

When demand exceeds capacity, some vehicles that arrive during T_p will depart during the next period. The time required to clear all vehicles arriving during T_p is shown above as T_c. Because the HCM defines delay in terms of the delay experienced by *all vehicles that arrive* during the analysis period, the delay computations must include the delay to those vehicles that arrive during T_p and depart during T_c.

The HCM defines delay in terms of the delay experienced by all vehicles arriving during an analysis period (e.g., 15 min), including delay accumulated after the end of the analysis period.

This definition differs from the delay definition used by most simulation tools, which address the delay experienced *during* the analysis period. The HCM definition includes the area within both triangles of Exhibit 7-12. The simulation definition includes only that portion of the area within the interval T_p.

Most simulation tools define delay in terms of the delay experienced by all vehicles during a specified analysis period and do not include delay from later time periods.

Compatibility with the HCM definition dictates that a control delay measure should be based on all entering vehicles, without regard to completed trips. An adequate initialization period should be used to load the facility. When the *d/c* ratio is less than 1.00, some vehicles that entered before the start of the analysis (i.e., during the initialization period) will exit the system. There will also be vehicles that enter the system late in the period and do not exit. Including these incomplete trips will not bias the delay results.

When demand exceeds capacity for a single period, the HCM delay formulation shown in Exhibit 7-12 will include the delay to vehicles that exit in the next period. The simulation results will not. To produce a simulation run that replicates the HCM single-period calculations, a second period with zero demand must be added to the simulation run. Only the vehicles that were unable to exit during the first period will be accommodated during the second period. The sum of the delays for both periods will be equivalent to the HCM delay shown in Exhibit 7-12.

Delay for Multiperiod Oversaturation

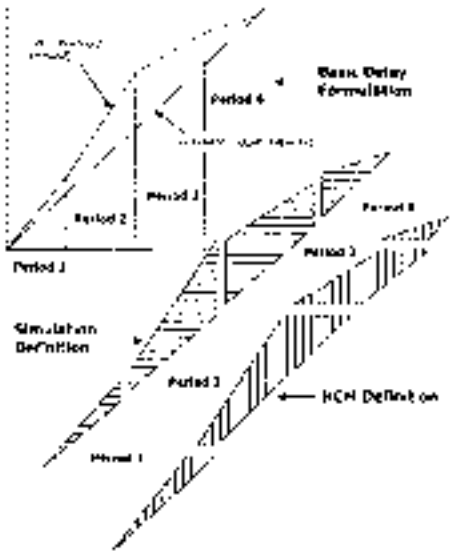
When operations are oversaturated beyond a single analysis period, a multiperiod analysis is necessary.

When the operation is oversaturated beyond a single period, it is necessary to perform a multiperiod analysis, ensuring that the duration is sufficient to encompass uncongestion conditions at both ends.

As an example, HCM and simulation delay formulations are illustrated in Exhibit 7-13, which depicts the analysis of four oversaturated periods that begin and end without congestion. The analysis is performed sequentially, with the residual queues from one period applied as initial queues to the next period. The first two periods have demand in excess of capacity. In the last two periods, the demand drops sufficiently below capacity to allow the queues to clear. Delay polygons are shown for the HCM and simulation definitions for all periods. The shape of the delay polygons differs in the two formulations, so the delay values are not the same for any period. The important thing is that the sum of the areas for the four polygons is the same for each definition.

AR0074009

Exhibit 7-13
Comparison of HCM and Simulation Delay Definitions for Four Oversaturated Periods



Therefore, to promote compatibility between the HCM and simulation delay definitions for a multiperiod analysis involving oversaturated signalized approaches, the simulation results should be obtained as follows.

- Ensure that the analysis period is long enough to encompass a period of congestion-free operation at both ends.
- Perform an adequate initialization to load the system.
- Perform the analysis on all vehicles entering the system during each period.
- Do not ignore any entering or exiting vehicle in any period; otherwise, the results could be biased.
- If a measure of delay per vehicle is desired, develop the total delay by summing the delays for the individual periods and divide that delay by the total entering volume.

Delay is not reported explicitly in the freeway segment chapters (Chapters 11 to 13). However, delay may be inferred from each chapter's free-flow and average speed computations. This step is performed in Chapter 10 for analysis of freeway facilities involving a combination of different segment types. The delay due to queues forming from bottlenecks is added to the individual segment delays. While the delay computations are conceptually simpler for freeways, the same guidance for developing compatible simulation results applies to other system elements.

Density is defined only in the uninterrupted-flow chapters. Unlike delay measures, which apply to individual vehicles, the density measure applies to the facility. Therefore, the issue of how to treat incomplete trips does not apply. Instantaneous densities should be determined from simulation by time step and should be aggregated over suitable intervals. The average density over a long period will be of less interest for most purposes than the variation of density that takes place in time and space. Typical aggregation intervals for that purpose will range from 5 to 15 min.

AR0074010

4. PRESENTATION OF RESULTS

GUIDANCE ON THE DISPLAY OF HCM RESULTS

Conventions for the display of results in the HCM.

Tabular values and calculated results are displayed in a consistent manner throughout the HCM. It is suggested that analysts adhere to these conventions. A key objective is to use the number of significant digits that is reasonable, to indicate to users, decision makers, and other viewers that the results are not extremely precise but take on the precision and accuracy associated with the input variables used. This guidance applies primarily to inputs and final outputs; intermediate results in a series of calculations should not be rounded unless specifically indicated by a particular methodology.

Input Values

Following is a list of representative (not exhaustive) input variables and the suggested number of digits for each:

- Volume (whole number);
- Grade (whole number);
- Lane width (one decimal place);
- Percentage of heavy vehicles (whole number);
- PHF (two decimal places);
- Pedestrian volume (whole number);
- Bicycle volume (whole number);
- Parking maneuvers (whole number);
- Bus stopping (whole number);
- Green, yellow, all-red, and cycle times (one decimal place);
- Lost time/phase (whole number); and
- Minimum pedestrian time (one decimal place).

Adjustment Factors

Factors interpolated from tabular material can use one more decimal place than is presented in the table. Factors generated from equations can be taken to three decimal places.

Service Volume Tables

When rounding volumes for service volume tables, a precision no greater than the nearest 10 vehicles or passenger cars should be used for hourly tables and the nearest 100 vehicles or passenger cars for daily tables.

Free-Flow Speed

For base free-flow speeds, show the value to the nearest 1 mi/h. For free-flow speeds that have been adjusted for various conditions and that are considered intermediate calculations, show speed to the nearest 0.1 mi/h.

AR0074011

Speeds

For threshold values that define LOS, show speed to the nearest 1 mi/h. For intermediate calculations of speed, use one decimal place.

Volume-to-Capacity and Demand-to-Capacity Ratios

Show v/c and d/c ratios with two decimal places.

Delay

In computing delay, show results with one decimal place. In presenting delay as a threshold value in LOS tables, show a whole number.

Density

Show density results with one decimal place.

Pedestrian Space

Show pedestrian space values with one decimal place.

Occurrences and Events

For all event-based items, use values to a whole number. These items include parking maneuvers, bus stops, events along a pedestrian or bicycle path, and number of cycles in a given time period.

General Factors

In performing all calculations on a computer, the full precision available should be used. Intermediate calculation outputs should be displayed to more significant digits throughout. For the measure that defines LOS, the number of significant digits presented should exceed by one the number of significant digits shown in the LOS table.

PRESENTING RESULTS TO FACILITATE INTERPRETATION

Performance measures selected should be related to the problem being addressed.

Several performance measures can result from HCM analyses. Determining the most appropriate measures to use for a decision depends on the particular case. However, decision-making situations generally can be divided into those involving the public (e.g., city councils and community groups) and those involving technicians (e.g., state and local engineering and planning staff).

The HCM is highly technical and complex. The results of the analyses can be difficult for people to interpret for decision making, unless the data are carefully organized and presented. In general, the results should be presented as simply as possible. This presentation might use a small set of performance measures and provide the data in an aggregate form without losing the ability to relate to the underlying variations and factors that generated the results.

The LOS concept was created, in part, to make presentation of results easier than if numerical values of service measures were reported directly. In many cases, analysts and decision makers prefer to see one service measure rather than multiple performance measures. At the same time, relying solely on LOS results in making recommendations or decisions can result in important information available from other performance measures being overlooked. Nevertheless,

AR0074012

although there are limitations to its usefulness, the LOS concept remains a part of the HCM because of its acceptance by the public and decision makers.

Decision makers who represent the public usually prefer measures that their constituents can understand; the public can relate to LOS results. Unit delay (e.g., seconds per vehicle) and travel speed are also readily understood. However, volume-to-capacity ratio, density, percent time spent following, and vehicle hours of travel are not measures to which the public easily relates. When the measures to present are selected, it is important for the analyst to recognize the orientation of the decision maker and the context in which the decision will be made. In general, these measures can be differentiated as system-user or system-manager oriented.

GRAPHIC REPRESENTATION OF RESULTS

Historically, data and analysis results have been presented primarily in tables. However, results may be best presented as pictures and supplemented only as necessary with the underlying numbers in some situations. Graphs and charts should not be used to decorate data or to make dull data entertaining; they should be conceived and fashioned to aid in interpretation of the meaning behind the numbers (17).

Present results to make them very plain (obvious) to the audience.

Most performance measures in the HCM are quantitative, continuous variables. LOS values, however, result from step functions and do not lend themselves to graphing. When placed on a scale, LOS results must be given an equivalent numeric value, as shown in Exhibit 7-14, which presents the LOS for a group of intersections. The LOS letter is indicated, and shaded (or colored) areas indicate intersections that are below, at, or above the analysis objective of LOS D. The size of the indicator at each intersection shows the relative control delay value for the indicated LOS.

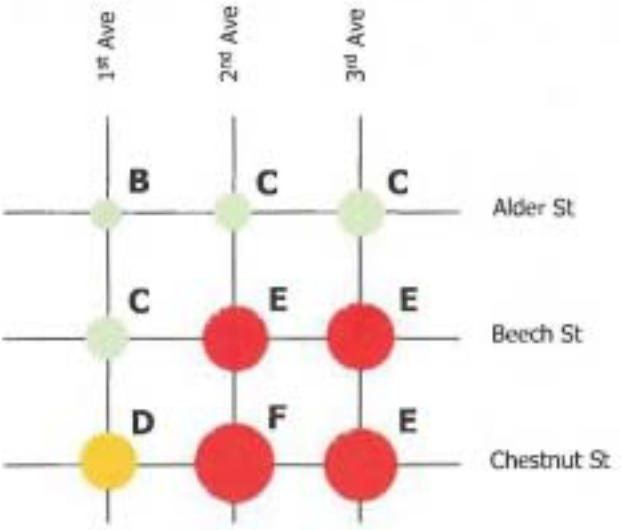


Exhibit 7-14
Example of a Graphic Display of LOS

AR0074013

The issue is whether the change in value between successive LOS values (i.e., the interval) should be equal. For instance, is it appropriate for LOS A to F to be converted to a scale of 0 through 5? Should the numerical equivalent assigned to the difference of the thresholds between LOS A and B be the same as the difference between LOS E and F? These questions have not been addressed in research, except in the area of traveler-perception models. Furthermore, LOS F is not given an upper bound. Therefore, a graph of LOS should be considered ordinal, not interval, because the numeric differences between the levels would not appear significant.

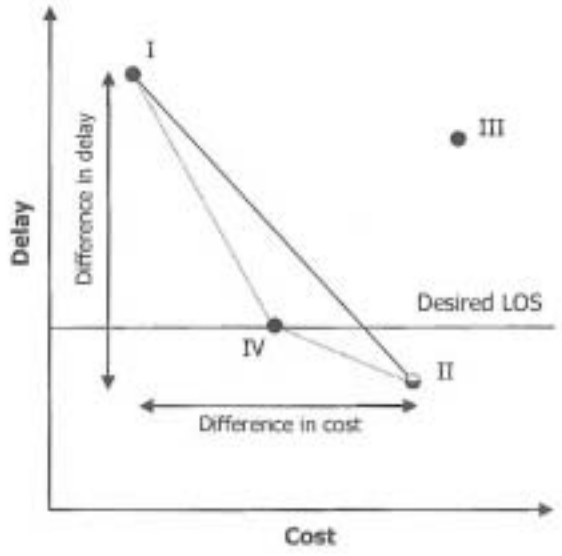
However, it is difficult to refrain from comparing the differences. A scale representing the relative values of the LOS letters would have to incorporate the judgment of the analyst and the opinions of the public or decision makers—a difficult task. A thematic graphic presentation, however, avoids this issue. In Exhibit 7-15, for example, shading is used to highlight time periods and basic freeway segments that do not meet the objective LOS (in this case, D).

Exhibit 7-15
Example of a Thematic Graphic Display of LOS

Start Time	Segment 1	Segment 2	Segment 3	Segment 4
5:00 p.m.	A	B	B	A
5:15 p.m.	B	B	D	A
5:30 p.m.	B	B	F	A
5:45 p.m.	B	D	F	A
6:00 p.m.	B	F	F	A
6:15 p.m.	D	F	E	A
6:30 p.m.	D	E	C	A
6:45 p.m.	B	B	B	A

Simple graphics often can facilitate decision making among available alternatives. For example, in the cost-effectiveness graph in Exhibit 7-16, the estimated delays resulting from alternative treatments are plotted against their associated cost. The graph shows more clearly than a tabulation of the numbers that Alternative III is more costly and creates higher delay than Alternative II. This result eliminates Alternative III.

Exhibit 7-16
Example of a Cost-Effectiveness Graph



AR0074014

Whether Alternative I or II should be chosen, however, is a matter for the decision maker's judgment. Alternative II is more expensive than Alternative I but is predicted to deliver a significantly lower delay. A useful measure for decision makers is provided by the slope of the line between the alternatives, which shows the seconds of delay saved per dollar of cost.

For this example, assume that Alternative IV provides the minimum acceptable LOS at significantly less cost than Alternative III. The dotted lines in Exhibit 7-7 indicate the relative cost effectiveness of moving from Alternative I to IV or Alternative IV to II. The steepest slope—I to IV—signifies a high level of cost effectiveness. The two alternatives that just exceed the LOS objective are Alternatives II and IV. The most appropriate alternative, therefore, is Alternative IV.

The HCM provides valuable assistance in making transportation management decisions in a wide range of situations. It offers the user a selection of performance measures to meet a variety of needs. The analyst should recognize that using the HCM involves mixing a bit of art along with the science. Sound judgment is needed not only for interpreting the values produced but also for summarizing and presenting the results.

The 2010 *Highway Capacity Manual* (HCM) is the fifth edition of this fundamental reference document. Its objectives are threefold:

1. To define performance measures and describe various methods for key traffic characteristics,
2. To provide methodologies to estimate and predict facility-related performance measures, and
3. To explain methodologies in a manner that allows readers to understand the factors that affect multimodal roadway operations.

The travel modes covered by the HCM consist of the *automobile*, *pedestrian*, and *bicycle* modes, as well as *public transit* vehicles that operate on urban streets. The automobile mode includes other motorized roadway users, such as trucks, recreational vehicles, intercity buses, and motorcycles.

HCM methodologies can be applied both to *uninterrupted-flow* roadways, such as freeways, multilane rural highways, and two-lane rural highways, and to *interrupted-flow* roadways, primarily urban streets and the intersections located along those streets. Methodologies are also provided for evaluating off-street pedestrian and bicycle facilities. The HCM can be applied to *under-saturated* conditions (where traffic demand is less than a roadway's capacity) and, in certain situations, to *over-saturated* conditions (where demand exceeds capacity).

The HCM 2010 presents the best available techniques at the time of publication for determining roadway capacity and level of service (LOS), proven to work in the United States and validated by a group of experienced experts. However, the HCM does not endeavor to establish a legal standard for highway design or construction.

Chapter 8, HCM Primer, is written for a nontechnical audience and is a synopsis of Volume 1 of the HCM. An example of a potential audience for this chapter is decision makers who may be presented with the results of HCM analyses for the purpose of establishing policy or public interest findings. The chapter covers basic traffic operations terminology, capacity and quality-of-service concepts, and guidance on applying the results of analyses produced by the HCM and alternative traffic operations tools.

AR0074021

2. HIGHWAY CAPACITY CONCEPTS

DEFINITION OF CAPACITY

Capacity is the maximum sustainable hourly flow rate at which persons or vehicles reasonably can be expected to traverse a point or a uniform section of a lane or roadway during a given time period under prevailing roadway, environmental, traffic, and control conditions. This one-sentence definition covers a variety of diverse topics, each discussed below:

- *Roadway conditions* include such factors as the number of lanes, the width of the lanes and shoulders, and the roadway's horizontal and vertical alignment. The addition of a lane to a freeway, for example, increases the freeway's capacity, while substandard lane and shoulder widths may result in a lower capacity than would standard widths.
- *Environmental conditions* include weather and lighting. The base conditions assumed in the HCM are good weather and lighting; however, depending on the needs of a given analysis (e.g., an analysis of travel time variability), roadway capacities under less than ideal conditions may be of interest. The HCM provides guidance for those situations as well.
- *Traffic conditions* include the proportion of heavy vehicles (i.e., trucks, buses, and recreational vehicles) in the traffic stream, the proportion of roadway users who are regular users, turning-movement patterns at intersections, and the distribution of vehicles between lanes and directions of a roadway. Heavy vehicles adversely affect traffic in two ways: (a) they occupy more roadway space than passenger cars and (b) they have poorer operating capabilities than passenger cars, particularly with respect to acceleration, deceleration, and the ability to maintain speed on upgrades.
- *Control conditions* include the types of traffic control used at intersections (i.e., traffic signals, stop signs, or YIELD signs), the amount of green time allocated to a particular movement at a traffic signal, and restrictions on the use of certain lanes (e.g., part-time restrictions on parking, or truck prohibitions on the left lane of a freeway).
- *Reasonable expectancy* is the basis for defining capacity. That is, the stated capacity for a given roadway element is one that can be achieved repeatedly during peak periods, rather than the absolute maximum flow rate that could be observed on such a roadway. Driver characteristics vary from region to region, and the absolute maximum flow rate can vary from day to day and from location to location.
- Finally, the *time period* used for analysis is typically the peak 15 min of the analysis hour. Traffic demands typically fluctuate over the course of an hour, so a roadway designed to accommodate hourly traffic demands may experience shorter-term peaks in demand that cause the roadway to break down. Once a roadway has broken down, it may take some time to recover. A 15-min analysis period accommodates most variations in flow without producing an excessively conservative estimate of capacity.

Traffic demands used in HCM analyses are typically expressed as flow rates that represent four times the peak 15-min traffic demand.

AR0074022

Persons per hour, passenger-car equivalents per hour, and vehicles per hour are measures that can define capacity, depending on the type of roadway element and the type of analysis being conducted. The concept of person flow is important (a) in making strategic decisions about transportation modes in heavily traveled corridors and (b) in detecting the role of transit and high occupancy-vehicle priority treatments. Person-capacity and person-flow weight each type of vehicle in the traffic stream by the number of occupants carried.

UNINTERRUPTED-FLOW ROADWAYS

Characteristics

Uninterrupted-flow roadways have no fixed causes of delay or interruptions to the traffic stream such as traffic signals. Freeways and their components operate under the purest form of uninterrupted flow. There are no fixed interruptions to traffic flow, and access is controlled and limited to ramp locations. Multilane highways and two-lane highways can also operate under uninterrupted flow in long segments; however, it may also be necessary to examine points along these highways where traffic may need to slow or stop (e.g., traffic signals, roundabouts, and STOP signs).

The traffic stream on uninterrupted-flow facilities is the result of individual vehicles interacting with each other and the facility's geometric characteristics. The pattern of flow is generally controlled only by the characteristics of the land uses that generate the traffic using the facility, although freeway management and operations strategies—such as ramp metering, freeway auxiliary lanes, truck lane restrictions, variable speed limits, and incident detection and clearance—can also influence traffic flow. Operations can also be affected by environmental conditions, such as weather or lighting, by pavement conditions, and by the occurrence of traffic incidents (1, 2).

"Uninterrupted flow" describes the type of facility, not the quality of the traffic flow at any given time. A freeway experiencing stop-and-go congestion, for example, is still an uninterrupted-flow facility, despite the congestion.

HCM Methodologies

The HCM provides methodologies for the following uninterrupted-flow system elements:

- *Freeway facilities*. An extended length of a single freeway composed of a set of connected basic freeway, weaving, and merge and diverge segments.
- *Basic freeway segments*. The portions of a freeway outside the influence area of any on- or off-ramps.
- *Freeway weaving segments*. The portions of a freeway where an on-ramp is closely followed by an off-ramp and entering or exiting traffic must make at least one lane change to enter or exit the freeway.
- *Freeway merge and diverge segments*. The portions of a freeway where traffic enters or exits without having to change lanes to enter or leave a through traffic lane.

AR0074023

- *Multilane highways.* Higher-speed facilities, with two or more lanes in each direction, without full access control (i.e., traffic enters and exits by means of at-grade intersections, which may or may not be signal controlled).
- *Two-lane highways.* Facilities with mostly one lane of travel per direction, with motorists using passing lanes, turnouts, or the opposing lane (where allowed by regulation and opposing traffic) to pass slower vehicles.

Performance Measures

The following are key performance measures used to evaluate the operation of uninterrupted-flow roadways:

- *Density* is typically defined by the average number of vehicles (or passenger car equivalents) per lane mile of roadway. The denser the traffic conditions, the closer vehicles are to each other and the harder it is for vehicles to change lanes or maintain a constant speed. Density is frequently used to evaluate freeways and multilane highways.
- *Speed* reflects how fast motorists can travel along a roadway. The speed that a motorist would travel along an uninterrupted-flow roadway under low-volume conditions is known as the *free-flow speed*. Drivers experience delay when their travel speed is less than the free-flow speed, which is a result of traffic demands approaching or exceeding the roadway's capacity. Speed is used to evaluate all kinds of uninterrupted-flow roadways.
- *Percent time spent following* is a measure specific to two-lane highways. It represents the freedom to maneuver and the comfort and convenience of travel. It is the average percentage of travel time that vehicles must travel in platoons behind slower vehicles because of the inability to pass.
- *Volume-to-capacity (v/c) ratio* reflects how close a roadway is operating to its capacity. By definition, the volume of traffic using a roadway cannot exceed the roadway's capacity. Therefore, the v/c ratio is actually a *demand-to-capacity (d/c) ratio*. However, v/c ratio is the historically used term. A v/c ratio that exceeds 1.00 indicates that more vehicles demand to use a roadway than can be accommodated. Observed volumes represent only the number of vehicles that are able to pass through a portion of roadway under existing conditions; these volumes may be constrained by bottlenecks elsewhere along the roadway. In contrast, *demand volumes* represent the number of vehicles that would be observed in the absence of any bottlenecks. Analyses that fail to account for demand volumes may result in a forecast of better future conditions than would actually occur.

INTERRUPTED-FLOW ROADWAYS

Characteristics

Interrupted-flow facilities have fixed causes of periodic delay or traffic stream interruption, such as traffic signals, roundabouts, and stop signs. Urban streets are the most common form of this kind of facility. Exclusive pedestrian and bicycle facilities are also treated as interrupted flow, since they may

AR0074024

occasionally intersect other streets at locations where pedestrians and bicyclists do not automatically receive the right-of-way.

The traffic flow patterns on an interrupted-flow facility are the result of vehicle interactions, the facility's geometric characteristics, the traffic control used at intersections, and the frequency of access points to the facility. Traffic signals, for example, allow designated movements to occur only during certain portions of the signal cycle (and, therefore, only during certain portions of an hour). This control creates two significant outcomes. First, time affects flow and capacity, since the facility is not available for continuous use. Second, the traffic flow pattern is dictated by the type of control used. For instance, traffic signals create platoons of vehicles that travel along the facility as a group, with significant gaps between one platoon and the next. In contrast, all-way STOP-controlled intersections and roundabouts discharge vehicles more randomly, creating small (but not necessarily usable) gaps in traffic at downstream locations (1, 3).

HCM Methodologies

The HCM provides methodologies for the following interrupted-flow system elements:

- *Urban street facilities*, which are extended sections of collector or arterial streets, and which include the impacts of traffic signals or other traffic control along the street. Urban street facilities are formed by two or more *urban street segments*, which are typically street sections extending from one traffic signal to the next, including the impact of the traffic signal at the far ("downstream") end of the segment. Roundabouts and STOP sign control on the major street can also define the end of an urban street segment. Segments are the basic analysis unit for multimodal analyses.
- *Signalized intersections*.
- *Interchange ramp terminals*, which are two closely spaced intersections of freeway ramps and surface streets. The HCM can be used to analyze interchange ramp terminals consisting of a pair of signalized intersections or a pair of roundabouts.
- *Unsignalized intersections*, including two-way STOP-controlled intersections (i.e., intersections where only the side street approaches are required to stop), all-way STOP-controlled intersections, and roundabouts.
- *On-street pedestrian and bicycle facilities*, such as bicycle paths or multiuse trails. On-street pedestrian and bicycle facilities are addressed by the methodologies for urban streets and intersections, although not every system element has an associated pedestrian or bicycle methodology.

AR0074025

Performance Measures

The following are key performance measures used in evaluating the operation of motorized vehicles on interrupted-flow roadways:

- *Control delay* is the delay incurred because of the presence of a traffic control device. It includes delay associated with vehicles slowing in advance of an intersection, the time spent stopped at intersection approach, the time spent as vehicles move through a queue, and the time needed for vehicles to accelerate to their desired speed once through the intersection.
- *Speed* reflects how fast motorists can traverse a roadway section, including the effects of traffic control devices, delays due to turning vehicles at intersections and driveways, and traffic demands on the roadway.
- *Number of stops* reflects how frequently motorists must come to a stop while traveling along an urban street because of traffic control, turning vehicles, midblock pedestrian crossings, and similar factors.
- *Queue length* reflects how far traffic backs up as a result of traffic control (e.g., a queue from a traffic signal) or a vehicle stopped in the travel lane while waiting to make a turn. Queuing is both an important operational measure and a design consideration. Queues that use storage from the available storage length can create several types of operational problems. A through-lane queue that extends past the entrance to a turn lane blocks access to the turn lane, keeping it from being used effectively. Similarly, a turn-lane queue overflow into a through lane interferes with the movement of through vehicles. Queues that extend upstream from an intersection can block access into and out of driveways and—in a worst case—can spill back into and block upstream intersections, causing side streets to begin to queue back.
- *Volume to capacity (demand to capacity) ratio*, which are defined and used similarly to those of uninterrupted-flow roadways.
- The performance measures produced by *traveler perception models* describe how travelers would perceive conditions. These models use a variety of inputs to generate a single performance measure. The measure value predicts the average perception rating that all users of a given mode would give a particular system element. Traveler perception models are frequently applied to pedestrian, bicycle, and transit analyses and are discussed further in Section 3, Quality and Level of Service Concepts.
- *Pedestrian space*, *bicycle speed*, and *number of meeting/passing events* on off-street pedestrian and bicycle facilities can also be of interest to analyses involving the pedestrian and bicycle modes.

MODAL INTERACTIONS

Roadways serve users of many different modes—in particular, motorists, pedestrians, bicyclists, and transit passengers. The roadway right-of-way is allocated among the modes through the provision of facilities that ideally serve each mode's needs. However, in many urban situations, the right-of-way is

AR0074026

constrained by adjacent land development, existing transportation networks and planners to consider trade-offs in how to allocate the right-of-way. Interactions among the modes that result from different right-of-way allocations are important to consider in analyzing a roadway and the HCM provides tools for assessing these interactions. Local policies and design standards relating to roadway functional classifications also provide guidance on the allocation of right-of-way; safety and operational concerns should also be addressed. Exhibit 8-1 summarizes some of the key interactions that occur between modes.

Exhibit 8-1
Mode Interaction Summary

Mode Creating the Interaction	Mode Affected by the Interaction			
	Automobile	**Pedestrian**	**Bicycle**	**Transit**
Automobile	Turning automobiles can delay other automobiles, heavy vehicles, bicycles, pedestrians, and transit vehicles. Traffic signal timing is influenced by relative traffic volumes on intersection approaches. Intersection delay tends to increase as automobile volume increases.	Cross-street automobile volumes influence traffic signal timing (and, therefore, delay), further increasing conflicts between vehicles and pedestrians. Automobile and heavy vehicle volumes and their associated separation from pedestrians create a sense	Automobile and heavy vehicle volumes and speeds, presence of crosstown parking, and the degree to which bicyclists are separated from vehicular traffic influence bicyclists' perception of comfort during interactions with automobiles at intersections.	Impacts similar to those of automobiles or automobiles; however, may be delayed waiting for a gap in traffic when they cross a bus stop. Higher volumes of traffic, volumes and transit operations in making or missing green lights affect schedule reliability.
Pedestrian	Minimum green times at traffic signals may be dictated by crosswalk lengths for automobiles and for crossing pedestrians.	Congestion when pedestrian flows intersect cause pedestrians to adjust their routes and travel speed; pedestrian space and comfort decrease as pedestrian volumes increase.	Pedestrians being met and passed by bicycles on multiuse paths affect overall comfort because of pedestrians' slower speeds and tendency to walk abreast on streets, effect on bicycles' view is that of automobiles.	Impacts similar to those of pedestrians on automobiles; transit riders are often pedestrians before and after their transit trip, so the quality of the pedestrian environment affects the perceived quality of the transit trip.
Bicycle	Turning automobiles yield to bicycles; automobiles may be delayed waiting to pass bicyclists in standard lane situations.	Bicycles meeting and passing pedestrians on multiuse paths affect pedestrians' comfort because of the bicycles' relatively higher speeds.	Bicyclists may be delayed when they need caution when overtaking, meeting, and passing events on cross-street roadways affect bicyclist comfort.	Impacts similar to those of automobiles on bicycles, but a bicycle's ability to travel at greater speeds than transit vehicles between stops affects the reach of a bicycle trip and allows a bike to be considered in the event of a flat tire or a
Transit	Stopping heavy vehicles, buses stopping in the travel lane to serve passengers can delay other vehicles. Transit signal priority measures affect the allocation of green time.	Impacts similar to those of automobiles on pedestrians, but produce a relatively greater effect due to transit vehicles' greater size.	Impacts similar to those of automobiles on bicycles, but a bicycle's ability to travel at greater speeds than transit vehicles between stops affects the reach of a bicycle trip and allows a bike to be considered in the event of a flat tire or a	Bus speeds decrease as bus volumes increase; in urban headways of more passenger cars on some buses and increase wait times for buses.

AR0074027

3. QUALITY AND LEVEL-OF-SERVICE CONCEPTS

OVERVIEW

There are many ways to measure the performance of a transportation facility or service, and many points of view that can be considered in making that measurement. The agency operating a roadway, automobile drivers, pedestrians, bicyclists, bus passengers, decision makers, and the community at large all have their own perspectives on how a roadway or service should perform and what constitutes "good" performance. As a result, there is not one right way to measure and interpret performance. The HCM provides a number of tools for describing how well a transportation facility or service operates from a traveler's perspective, a concept termed *quality of service*. One important tool for describing quality of service is the concept of LOS, which facilitates the presentation of results through the use of a familiar A (best) to F (worst) scale. A variety of specific performance measures, termed *service measures*, are used to determine LOS. These three concepts—quality of service, LOS, and service measures—are the topics of this section.

QUALITY OF SERVICE

Quality of service describes how well a transportation facility or service operates from a traveler's perspective.

Quality of service describes how well a transportation facility or service operates from a traveler's perspective. Quality of service can be assessed in a number of ways, including directly observing factors perceivable by and important to travelers (e.g., speed or delay), surveying travelers, tracking complaints and compliments about roadway conditions, forecasting traveler satisfaction by using models derived from past traveler surveys, and observing things not directly perceived by travelers (e.g., average time to clear a crash) that affect things they can perceive (e.g., speed or arrival time at work).

The HCM's focus is on the travel time, speed, delay, ability to maneuver, and comfort aspects of quality of service. Travel time reliability is expected to be added in the future, as a result of funded research. Other aspects of quality of service covered to a lesser degree by the HCM, or covered more thoroughly by its companion documents, include convenience of travel, safety, user cost, availability of facilities and services, roadway aesthetics, and information availability.

Dimensions of system performance and mobility.

Quality of service is one dimension of mobility and overall transportation system performance. Other dimensions to consider are the following (*6, 7*):

- *Quantity of service*—such as the number of person miles and person-hours provided by the system;
- *Capacity utilization*—including the amount of congestion experienced by users of the system, the physical length of the congested system, and the number of hours that congestion exists; and
- *Accessibility*—for example, the percentage of the population able to complete a selected trip within a specified time.

AR0074028

LEVEL OF SERVICE

LOS is the stratification of quality of service.

The HCM defines LOS for most combinations of travel mode (i.e., automobile, pedestrian, bicycle, and transit) and roadway system element (e.g., freeway, urban street, intersection) addressed by HCM methodologies. Six levels are defined, ranging from A to F. LOS A represents the best operating conditions from the traveler's perspective and LOS F the worst. For cost, environmental impact, and other reasons, roadways and transit services are not typically designed to provide LOS A conditions during peak periods. Rather, a lower LOS that reflects a balance between individual travelers' desires and society's desires and financial resources is typically the goal. Nevertheless, during low-volume periods of the day, a system element may operate at LOS A.

LOS is used to translate complex numerical performance results into a simple A–F system representative of the travelers' perceptions of the quality of service provided by a facility or service. The LOS letter result hides much of the complexity of facility performance to simplify decision making about whether facility performance is generally acceptable and whether a change in this performance is likely to be perceived as significant by the general public. One of the strengths of the LOS system, and a reason for its widespread adoption by agencies, is its ability to communicate roadway performance to laypersons. However, LOS has other strengths and weaknesses, described below, that both analysts and decision makers need to be mindful of.

Step Function Nature of LOS

Setting performance standards on the basis of LOS for any facet (average delay, for example) means that small changes in performance can sometimes result in the demand being exceeded, when a facility is already operating close to the standard.

The measure of effectiveness for automobiles at traffic signals is the average delay experienced by motorists. As traffic volumes on certain critical approaches increase, so does the average delay. The added delay may or may not result in a change in LOS. An increase of delay of 12 s may result in no change in LOS, a drop of one LOS level, or a drop of two LOS levels, depending on the starting value of delay. Because there are only six possible LOS letters, each covering a range of possible values, the reported LOS does not change until the service measure increases past the threshold value for a given LOS. A change of LOS indicates that roadway performance has transitioned from one given range of traveler-perceivable conditions to another range, while no change in LOS indicates that conditions are in the same performance range as before. The service measure value—in this case, average delay—indicates more specifically where conditions lie within a particular performance range.

Because a small change in a service measure can sometimes result in a letter change in the LOS result, the LOS result may imply a more significant effect than actually occurred. This aspect of LOS can be a particularly sensitive issue when agencies define their performance standards on the basis of LOS, since a small change in performance can trigger the need for potentially costly improvements. However, this issue exists whenever a fixed standard is used, whether or not LOS is the basis of that standard.

AR0074029

Uncertainty and False Precision

Computer software is frequently used to perform traffic operations analyses, and software can report results to many decimal places. However, such precision is often unjustified for four reasons:

1. In contrast to the force of gravity or the flow of water through a pipe, the actions of motorists driving on a roadway can vary. Traffic operations models predict average values of performance measures; the actual value for a measure on a given day may be somewhat higher or lower. Thus, the result reported by every traffic operations model has some uncertainty associated with it.
2. A given traffic operations model may rely on the output of other models that have their own associated result uncertainties.
3. Some model inputs, such as traffic volumes, are taken to be absolute, when there is actually variation in the inputs from month to month, day to day, or even within an hour. Traffic volumes, for example, may vary by 5% to 10% from one weekday to the next.
4. Some HCM models predict traveler perceptions. Two travelers who experience identical conditions may perceive those conditions differently. When many travelers are surveyed, a distribution of responses from "very satisfied" to "very dissatisfied" (or some similar scale) results. The traveler-perception models predict the average of those responses.
5. Some alternative tools involve the use of simulation, in which results will vary as inputs are randomly varied within a set distribution and average. Therefore, reporting only one result from simulation simplifies the actual results produced.

Therefore, any reported traffic operations performance measure value, whether resulting from an HCM methodology, an alternative tool (e.g., simulation), or even field measurement, potentially has a fairly wide range associated with it in which the "true" value actually lies. The LOS concept helps to downplay the implied accuracy of a numeric result by presenting a range of measure results as being reasonably equivalent from a traveler's point of view. However, the same variability issues also mean that the "true" LOS value may be different from the one predicted by a methodology. One way of thinking about a reported value and its corresponding LOS result is that they are the statistical "best estimators" of conditions.

LOS Reported Separately by Mode

In an effort to provide a single top-level measure of conditions, some HCM users may be tempted to blend the LOS reported for each mode into a single LOS value for a roadway element. However, each mode's travelers have different perspectives and could experience different conditions while traveling along a particular roadway. The use of a blended LOS carries the risk of overlooking quality-of-service deficiencies for nonautomobile travelers that discourage the use of those modes, particularly if the blended LOS is weighted by the number of auto travelers. Other measures, such as person delay, can be used when an

AR0074030

analysis requires a combined measure. The HCM recommends reporting modal LOS results individually.

Reporting the Big Picture

Neither LOS nor any other single performance measure tells the full story of roadway performance.

Analysts and decision makers should always be mindful that neither LOS nor any other single performance measure tells the full story of roadway performance. Depending on the particulars of a given location and analysis, queue lengths, demand-to-capacity ratios, average travel speeds, indicators of safety, and other performance measures may be equally or even more important to consider, regardless of whether they are specifically called out in an agency standard. For this reason, the HCM provides methods for estimating a variety of typical roadway operations performance measures, and not just methods for determining LOS.

SERVICE MEASURES

Service measures are the performance measures that define LOS.

As introduced earlier, service measures are specific performance measures that are used to determine LOS. Exhibit 8-2 summarizes the service measures used by the HCM for different combinations of transportation system elements and travel modes. Some service measures are based on a traveler-perception model; the components of each model are given in Exhibit 8-3.

Exhibit 8-2
Service Measures by Individual System Element

System Element	Service Measures			
	Automobile	Pedestrian	Bicycle	Transit
Freeway facility	Density	--	--	--
Basic freeway segment	Density	--	--	--
Freeway weaving segment	Density	--	--	--
Ramp junction	Density	--	--	--
Multilane highway	Density	--	LOS score[a]	--
Two-lane highway	Percent time spent following, speed	--	LOS score[a]	--
Urban street facility	Speed	LOS score[a]	LOS score[a]	LOS score[a]
Urban street segment	Speed	LOS score[a]	LOS score[a]	LOS score[a]
Signalized intersection	Delay	LOS score[a]	LOS score[a]	--
Two-way stop	Delay	Delay	--	--
All-way stop	Delay		--	
Roundabout	Delay	--	--	--
Interchange ramp terminal	Delay	--	--	--
Off-street pedestrian bicycle facility		Space, speed[b]	LOS score[a]	--

Notes: [a] See Exhibit 8-3 for the LOS score components.
[b] Events on, speed on shared-use paths where pedestrians meet bicycles.

AR0074031

Exhibit 8-3
Components of Traveler-Perception Models Used to Generate Service Measures

System Element	Mode	Model Components
Multilane highway and freeway	Bicycle	Perceived separation between bicycles and motor vehicles, pavement quality, automobile and heavy vehicle volume and speed
Urban street facility	Automobile	Weighted average of segment and intersection LOS scores
	Pedestrian	Driveway per segment and signalized intersection pedestrian LOS scores, midblock crossing difficulty
	Bicycle	Urban street segment and signalized intersection bicycle LOS scores, driveway density
	Transit	Weighted average of segment (transit) LOS scores
Urban street segment	Automobile	Stops per mile, delay, lane presence
	Pedestrian	Pedestrian density, sidewalk width, perceived separation between pedestrians and motor vehicles, motor vehicle volume and speed
	Bicycle	Perceived separation between bicycles and motor vehicles, pavement quality, automobile and heavy vehicle volume and speed
	Transit	Service frequency, perceived speed, pedestrian LOS
Signalized intersection	Pedestrian	Street crossing delay, pedestrian exposure to turning vehicle conflicts, crossing distance
	Bicycle	Perceived separation between bicycles and motor vehicles, crossing distance
Off-street pedestrian/bicycle facility	Bicycle	Average meetings/minute, active passings/minute, path width, centerline presence, delayed passings

Note: The automobile mode has prior models for urban street segments and facilities that used to determine LOS; however, it is provided as a performance measure for multimodal analyses.

AR0074032

4. ANALYSIS PROCESS

LEVELS OF HCM ANALYSIS

The HCM can be applied at the *operational, planning and preliminary engineering,* and *design* analysis levels. The required input data typically remain the same at each analysis level, but the degree to which default values are used instead of measured or forecast values differs. In addition, operational and planning and preliminary engineering analyses frequently evaluate the LOS that will result from a given set of inputs, while design analyses evaluate the facility characteristics that will be needed to achieve a desired LOS.

Operational Analysis

In an operational analysis, an analyst applies an HCM methodology directly and supplies all of the required input parameters from measured or forecast values. No, or minimal, default values are used. Of the available ways to apply HCM methodologies, operational analyses provide the highest level of accuracy but, as a result, also require the most detailed data collection, which has time and cost implications.

An operational analysis helps in making decisions about operating conditions. Typical alternatives consider, for example, changes in traffic signal timing and phasing, changes in lane configurations, spacing, and location of bus stops, the frequency of bus service, or the addition of a bicycle lane. The analysis produces operational measures that can be used to compare the alternatives.

As discussed earlier in this chapter, even though a model's results may be highly accurate, any variability associated with the model's inputs can affect the model's results.

Planning and Preliminary Engineering Analysis

In planning and preliminary engineering analyses, an analyst applies an HCM methodology by using default values for some to nearly all of the model inputs—for example, through the use of generalized service volume tables. The results are less accurate than in an operations analysis, but the use of default values reduces the amount of data collection and the time required to perform an analysis. In a large-scale planning study, where a large number of roadways may be evaluated, this level of analysis may be the best practical, given time and budget constraints. For future-focused studies, not all of the model inputs may be known or forecastable, which suggests the need for a planning analysis with the use of default values for the unknown model inputs.

Planning analyses are applications of the HCM generally directed toward broad issues such as initial problem identification (e.g., screening a large number of locations for potential operations deficiencies), long-range analyses, and statewide performance monitoring. An analyst often must estimate the future times at which the transportation system will fall below a desired LOS. Preliminary engineering analyses are often conducted to support planning decisions related to a roadway design concept and scope and to perform alternatives analyses. These studies can also assess proposed system policies.

AR0074033

such as lane-use control for heavy vehicles, systemwide freeway ramp metering and other intelligent transportation systems applications, and the use of demand management techniques, such as congestion pricing (5).

Generalized Service-Volume Tables

Generalized service-volume tables are sometimes used in planning analyses. These tables are constructed by applying default values to an HCM methodology and then incrementally determining the maximum number of vehicles that a roadway could carry at a given LOS, given the assumed conditions.

Service-volume results should be applied with care, since actual conditions will likely vary in some way from the assumptions used to develop the table.

The use of a service volume table is most appropriate in situations in which it is not practical to evaluate every roadway or intersection within a study area. Examples of these applications would be city, county, or statewide planning studies, where the size of the study area makes it infeasible to conduct a capacity or LOS analysis for every roadway segment. For these types of planning applications, the focus of the effort is simply to highlight potential problem areas (for example, locations where demand may exceed capacity or where a desired LOS may be exceeded). For such applications, a service-volume table can be a useful screening tool. Once potential problem areas have been identified, more detailed analyses can be performed for those locations.

The HCM provides generalized service-volume tables for
- *Freeway facilities*
- *Multilane highways*
- *Two-lane highways*
- *Urban street facilities*

The characteristics of any given roadway will likely vary in some way from the assumed input values used to develop a service volume table. Therefore, the results from a service volume table should be treated as rough approximations. Service volume tables should not be substituted for other tools to make a final determination of the operational adequacy of a particular roadway.

Design Analysis

Design analyses typically apply the HCM to establish the detailed physical features that will allow a new or modified roadway to operate at a desired LOS. Design projects are usually targeted for mid- to long-term implementation. Not all the physical features that a designer must determine are reflected in the HCM models. Typically, analysts using the HCM are seeking to determine such elements as the basic number of lanes required and the need for auxiliary or turning lanes. However, an analyst can also use the HCM to establish values for elements such as lane width, steepness of grade, the length of added lanes, the size of pedestrian queuing areas, the widths of sidewalks and walkways, and the presence of bus pullouts.

The data required for design analyses are detailed and are based substantially on proposed design attributes. However, the intermediate- to long-term focus of the work will require the use of some default values. This simplification is justified in part by the limits on the accuracy and precision of the traffic forecasts with which the analyst will be working.

AR0074034

ANALYSIS TOOL SELECTION

Types of Tools

Each analytical or simulation tool, depending on the application, has its own strengths and weaknesses. It is important to relate relevant modeling features to the needs of the analyses and to determine which tool satisfies those needs to the greatest extent.

HCM methodologies are deterministic and macroscopic. A deterministic model will always produce the same result for a given set of inputs. A macroscopic model considers average conditions experienced by vehicles over a period of time (typically 15 min or 1 h). In comparison, microsimulation models are stochastic and microscopic. In a stochastic model, a different random number seed will produce a different modeling result; therefore, the outcome from a simulation run based on a stochastic model cannot be predicted with certainty before the analysis begins. Microscopic models simulate the movement of individual vehicles on the basis of car-following and lane-changing theories.

Situations When Alternative Tools Might Be Considered

The HCM is the product of a large number of peer-reviewed research projects and reflects the best available techniques (at the time of publication) for determining capacity and LOS. However, the research behind the HCM has not addressed every possible situation that can arise in the real world. Therefore, the HCM documents the limitations of its procedures and highlights situations when alternative analysis tools should be considered to supplement or substitute for the HCM. The following are examples of these situations:

- The configuration of the facility has elements that are beyond the scope of the HCM procedures. Each HCM procedural chapter identifies the specific limitations of its own methodology.
- Viable alternatives being considered in the study require the application of an alternative tool to make a more informed decision.
- The measures are incompatible with corresponding HCM measures and the decision process requires additional performance measures, such as fuel consumption and emissions, that are beyond the scope of the HCM.
- The system under study involves a group of different facilities with mutual interactions that require the use of more than one HCM chapter. Alternative tools are able to analyze these facilities as a single system.
- Routing is an essential part of the problem being addressed.
- The quantity of input or output data required presents an intractable problem for the HCM procedures.
- The HCM procedures predict oversaturated conditions that last throughout a substantial part of a peak period or queues that overflow the available storage space.

The Federal Highway Administration's Traffic Analysis Toolbox (6) provides general guidance on the use of traffic analysis tools, including the HCM. More detailed guidance for alternative tool application to specific system elements is

AR0074035

presented in Volumes 2 and 3 of the HCM. Supplemental examples involving situations beyond the scope of the HCM procedures are presented in Volume 4.

INTERPRETING RESULTS

Uncertainty and Variability

Model outputs—whether from the HCM or alternative tools—are estimates of the "true" values that would be observed in the field. Actual values will fall within some range of the estimated value. The magnitude of the range, and therefore the degree of uncertainty, is a function of several variables, including the quality of the input data, the inherent variability of the model, and the degree to which the model accounts for all of the factors that govern the analysis. The uncertainty may be compounded to some extent by imperfect knowledge of the traveler perception aspects of quality of service.

When stochastic simulation tools are used, uncertainty is normally addressed through multiple runs with different random number seeding. Regardless of the modeling approach, a sensitivity analysis may be performed to assess the degree to which input data variation is likely to affect the range of performance measure outputs. Depending on the model and the specifics of the situation being modeled, small changes in model inputs can have large impacts on model outputs.

Accuracy and Precision

Accuracy and precision are independent but complementary concepts. *Accuracy* relates to achieving a correct answer, while *precision* relates to the size of the estimation range of the procedure in question. In most cases, the field data on which the analyses are based can only be expected to be accurate to within 5% or 10% of the true value. Thus, the computations performed with these inputs cannot be expected to be extremely accurate, and the final results must be considered as estimates that are accurate and precise only within the limits of the inputs used.

HCM users should be aware of the limitations of the accuracy and precision of the methodologies in the manual. Such awareness will help users interpret the results of an analysis and use the results to make a decision on the design or operation of a transportation facility.

Comparing HCM Results with Alternative Tools

The exact definitions of performance measures are an important issue, particularly when a comparison of performance measures produced by different tools is to be made. Many tools produce performance measures with the same name (e.g., "delay"), but the definitions and methods of computation can differ widely. Chapter 7, Interpreting HCM and Alternative Tool Results, presents general guidance on comparing results. The procedural chapters in Volumes 2 and 3 present guidance on this topic for specific system elements.

AR0074036

Use of Vehicle Trajectory Analysis in Determining Performance Measures

It was pointed out in Chapter 6, Traffic Flow and Capacity Concepts, that the analysis of individual vehicle trajectories is becoming recognized as the most desirable method of producing performance measures that are consistent among different tools and comparable with the measures produced by the analysis procedures given in this manual. The HCM provides trajectory-based definitions and computational procedures for all of the commonly used performance measures. Alternative tool developers are encouraged to incorporate these definitions and computations into their products. Users of this manual are encouraged to consider the degree to which the performance measures comply with the HCM specifications in their traffic analysis tool selection process.

Temporal and Spatial Boundaries

Another source of difference in the performance measures obtained from different tools lies in their treatment of incomplete trips. Incomplete trips include those that enter a facility during a given analysis period and exit during a subsequent period and those that exit a facility after entering in a previous analysis period. To overcome differences among analysis tools, it is important that the analysis period cover enough time and space to include an uncongested interval at all boundaries.

When undersaturated operation is being studied, the definition of the facility in time and space is less important. The operation tends to be more homogeneous when the ratios are less than 1.00. For most performance measures, extending the analysis period will give a larger sample of vehicles, but it will not affect the performance measures significantly.

PRESENTING RESULTS

Tabular values and calculated results are displayed in a consistent manner throughout the HCM. It is suggested that analysts adhere to these conventions. A key objective is to use a number of significant digits indicating to users, decision makers, and other viewers that the results are not extremely precise but take on the precision and accuracy associated with the input variables used. This guidance applies primarily to inputs and final outputs; intermediate results in a series of calculations should not be rounded unless specifically indicated by a particular methodology.

Historically, data and analysis results have been presented primarily in tables. However, results may be best presented as pictures and only supplemented as necessary with the underlying numbers in some situations. Graphs and charts should not be used to decorate data or to make dull data entertaining; they should be conceived and fashioned to aid in the interpretation of the meaning behind the numbers.

AR0074037

5. DECISION-MAKING CONSIDERATIONS

The HCM provides procedures for capacity and quality-of-service analyses and therefore serves as an analytical tool for transportation engineers and planners. The 2010 edition of the HCM presents the best available techniques at the time of publication for determining roadway capacity and LOS, proven to work in the United States and validated by a group of independent experts. However, the HCM is only a guidance document; it does not endeavor to establish a legal standard for highway design or construction. This section describes the role of other guidance and standards documents that complement the HCM, along with issues for decision makers to consider should they choose to adopt HCM service measures as standards.

ROLE OF HCM COMPANION DOCUMENTS

Throughout its 60 year history, the HCM has been a fundamental reference work for transportation engineers and planners. However, it is but one of a number of documents that play a role in the planning, design, and operation of transportation facilities and services. The HCM's scope is to provide tools to evaluate the performance of highway and street facilities in terms of operational and traveler-perception measures. This section describes companion documents to the HCM that cover important topics outside the HCM's scope.

Highway Safety Manual

The *Highway Safety Manual* (HSM) (7) provides analytical tools and techniques for quantifying the safety effects of decisions related to planning, design, operations, and maintenance. The information in the HSM is provided to assist agencies as they integrate safety into their decision making processes. It is a nationally used resource document intended to help transportation professionals conduct safety analyses in a technically sound and consistent manner, thereby improving decisions made on the basis of safety performance.

A Policy on Geometric Design of Highways and Streets

The American Association of State Highway and Transportation Officials' (AASHTO's) *A Policy on Geometric Design of Highways and Streets* ("Green Book") (8) provides design guidelines for roadways ranging from local streets to freeways, in both urban and rural locations. The guidelines "are intended to provide operational efficiency, comfort, safety, and convenience for the motorist," while also emphasizing the need to consider the use of roadway facilities by other modal users.

Manual on Uniform Traffic Control Devices

The Federal Highway Administration's *Manual on Uniform Traffic Control Devices for Streets and Highways* (MUTCD) (9) is the national standard for traffic control devices for any street, highway, or bicycle trail open to public travel. Of particular interest to HCM users are the sections of the MUTCD pertaining to warrants for all-way stop control and traffic-signal control, signing and

AR0074038

markings to designate lanes at intersections and associated considerations of adequate roadway capacity and less restrictive intersection treatments.

Transit Capacity and Quality of Service Manual

The *Transit Capacity and Quality of Service Manual* (TCQSM; 10) is the transit counterpart to the HCM. The TCQSM contains information on the various types of public transportation and provides a framework for measuring transit availability, comfort, and convenience from the passenger point of view. The manual contains quantitative techniques for calculating the capacity of bus, rail, and ferry transit services and of transit stops, stations, and terminals.

TOOLS VERSUS STANDARDS

Although the HCM does not set standards—for example, it does not specify a particular LOS that should be provided for a particular roadway type—it is referenced in the AASHTO Green Book (9), and numerous agencies and jurisdictions have adopted LOS standards based on the HCM. This section discusses issues that agencies and jurisdictions should consider when they adopt standards or guidance relating to LOS or default values used in HCM analyses.

Evolution of HCM Analysis Procedures

Each new edition of the HCM has incorporated new methodologies and—in some cases—new service measures for evaluating roadway system elements. This edition of the HCM is no different.

Changes in HCM methodologies are made to improve estimates of service and other performance measures. These types of changes do not directly affect an agency's adopted LOS standards, since the service measure for a particular roadway element and the threshold values for particular levels of service do not change. However, methodological changes frequently have indirect effects. For example, the estimated service measure value for a particular roadway might have met an agency's LOS standard under the previous methodology but might not meet the standard under the new methodology, and vice versa. Similarly, agencies that have adopted generalized service-volume tables may find that the service volumes associated with a given LOS have changed as a result of the methodological change. In this situation, the underlying estimate of the roadway's operation will not have changed, but the estimate of the traffic volume that produces that operation will have changed.

Even when the basic methodology for a roadway element does not change, the recommended default values for the methodology may have changed, which can also cause the issues described above with service volume tables and with old and new methodologies producing different results. Following the HCM's recommendations of using field-measured input values whenever possible and locally generated default values otherwise avoids this issue.

A service measure's LOS thresholds or the measure itself may change from one edition of the HCM to the next. In that case, it is recommended that an agency that has adopted an operations standard for that measure revisit the standard to ensure that it still accurately represents the quality of service the agency wishes to provide. These kinds of changes in the HCM may also have

AR0074039

planning and project programming implications, as the need for or scale of a given project may change.

Incorporating HCM Analysis Results into Decision Making

Agencies and jurisdictions adopt roadway design and operations standards for a number of reasons, including consistency in roadway design across a jurisdiction and provision of an objective basis for making decisions on required improvements. As mentioned earlier, numerous agencies and jurisdictions have chosen to adopt LOS standards for their roadways. The existence of computerized tools that implement HCM procedures makes it easy for analysts to test a number of roadway improvements against an LOS standard. However, the analysis does not end once an LOS result has been determined.

The existence of a LOS F condition does not, by itself, indicate that action must be taken to correct the condition. Conversely, meeting a LOS standard does not necessarily mean that no problem exists or that an improvement that produces the desired LOS is a desirable solution. Other issues, including but not limited to safety, impacts on other modes, traffic signal warrants, turn-lane warrants, cost–benefit issues, and access management, may also need to be considered as part of the analysis, recommendations, and eventual decision. As always, engineering judgment should be applied to any recommendations resulting from HCM (or alternative tool) analyses.

Two examples of common situations where a LOS result considered by itself might lead to a decision different from one that would be reached if other factors were also considered are given below.

Traffic Signal Warrants

The MUTCD (9) provides a number of warrants that indicate when a traffic signal may be justified. It is possible to have a condition at a two-way stop intersection—particularly when a low-volume minor street intersects a very high-volume major street—where the minor street approach operates at LOS F but does not meet traffic signal warrants. Because the MUTCD is the standard for determining when a traffic signal is warranted, a LOS F condition by itself is not sufficient justification for installing a signal.

Turn-Lane Warrants

A number of agencies and jurisdictions have adopted warrants that indicate when the installation of turn lanes may be justified at an intersection. It is possible for an HCM analysis to indicate that the addition of a turn lane will result in an acceptable LOS but for the turn-lane warrant analysis to determine that the necessary conditions for installing a turn lane have not been satisfied. In this case, the potential for a satisfactory LOS in the future would not be sufficient justification by itself for installing the turn lane.

2. LIST OF SYMBOLS 9-23

AR0074043

1. GLOSSARY

Chapter 9, Glossary and Symbols, defines the terms used in the *Highway Capacity Manual* (HCM) and presents the symbols and abbreviations used in the manual. Highway transportation terminology has evolved over time to create multiple definitions, and the confusion has been compounded by technical jargon. The definitions, abbreviations, and symbols presented here are intended to establish a consistent terminology for use in the HCM. It is recognized that other definitions and usage could exist.

VOLUME 1: CONCEPTS
1. HCM Users Guide
2. Applications
3. Modal Characteristics
4. Traffic Flow and Capacity Concepts
5. Quality and Level-of-Service Concepts

7. Interpreting HCM and Alternative Tool Results
8. HCM Primer
9. Glossary and Symbols

Acceleration lane – A speed-change lane including tapered areas, allowing vehicles to accelerate to the speed they enter the through traffic stream of the roadway.

Acceleration/deceleration delay – Delay experienced by vehicles slowing from and subsequently returning to their running speed.

Access point – An intersection, driveway, or opening onto the side of a roadway.

Access-point density – The total number of access points on both sides of the roadway, divided by the length of the segment.

Accessibility – The percentage of the population able to complete a selected trip within a specified time.

Accuracy – The degree of a measure's agreement with a standard or true value.

Active grass days – The number of days with more than 1 in. (25 mm) of rainfall during the growing season.

Average pace – The average speed of all bicyclists traveling at the average speed of all bicyclists traveling at the average speed of all bicyclists who are passed by that bicyclist.

Active priority – A form of traffic signal priority that adjusts signal timing in response to the arrival of a bus.

Active traffic management (ATM) – The dynamic and systematic monitoring and control of traffic conditions on a facility to improve its performance.

Actuated control – Control mode for which the green phase is in which the green time of each phase is dependent on whether the phase is on recall or the associated traffic movement has submitted a call for service through a detector.

Adjustment – An additive or multiplicative quantity that adjusts a parameter for a base condition to represent a prevailing condition.

Adjustment factor – A factor that adjusts a parameter for a base condition to represent prevailing condition.

Aggregate delay – The summed total of delays for multiple lanes or lane groups, usually aggregated for an approach, an intersection, or a arterial route.

Algorithm – A set of rules for solving a problem in a finite number of steps.

All-way stop-controlled (AWSC) intersection – An intersection with STOP signs on all approaches. The driver's decision to proceed is based on a consensus right-of-way governed by the traffic rules. Based on the other approaches and the rules of the road (e.g., the driver on the right has the right-of-way if two vehicles arrive simultaneously).

Alternative tool – Any analysis procedure outside of the HCM that may be used to evaluate measures of transportation system performance for analysis and decision support.

Analysis hour – A single hour for which a capacity analysis is performed for a system element.

Analysis period – A single time period (for example, the peak 15 min of the peak hour) during which a capacity analysis is performed for a system element.

Analytical model – A model based on traffic flow theory, combined with the use of field measures of driver behavior, resulting in an analytic formulation of the relationship between the field measures and performance measures such as capacity and delay.

Annual average daily traffic (AADT) – The total volume of traffic passing a point or segment of a highway facility in both directions for 1 year, divided by the number of days in the year.

AR0074045

Approach – A set of lanes at an intersection that accommodates all of the turn, through, and right-turn movements from a given direction.

Approach delay – The control delay for a given approach.

Approach grade – The average grade along the approach, as measured from the stop line on a point 100 ft upstream of the stop line along a line parallel to the direction of travel. An uphill condition has a positive grade, and a downhill condition has a negative grade.

Area – An interconnected set of transportation facilities serving movements within a specified geographic space, as well as movements to and from adjoining areas.

Area type – A description of the environment in which a system element is located.

Arrival rate – The measure of the statistical distribution of vehicles arriving at a point or midblock segment of an urban street.

Arrival type – Six assigned categories for the quality of progression for a given approach to a signalized intersection.

Arterial street – A street primarily controlled by traffic control devices (e.g., signals, stop signs, or yield signs) that primarily serves through traffic and that secondarily provides access to abutting properties. It also may serve transit.

Automobile mode – A travel mode that includes all motor vehicle traffic using a roadway except for transit buses. It includes only vehicles such as trucks, recreational vehicles, motorcycles, and tour buses.

Auxiliary lane – See freeway auxiliary lane.

Available time-space – The product of available time and available space for pedestrian circulation on a crosswalk or a signalized intersection.

Average bus stop spacing – The average distance between bus stops along a street.

Average grade – The rise from the beginning of the composite grade to the point of interest, divided by the length of the grade (to the point of interest).

Average running speed – The length of a segment divided by the average running time of vehicles that traverse the segment.

Average spot speed – See time-mean speed.

Average travel speed – The length of the highway segment divided by the average travel time of all vehicles traversing the segment, including all stopped delay times. Equal to space-mean speed.

B

Back of queue – The maximum backward distance (in feet) from vehicles during a typical cycle, as measured from the stop line to the last queued vehicle.

Barrier – 1. A separation of intersecting movements in different rings to prevent operation of conflicting phases at the same time. 2. A physical object or pavement marking designed to prevent vehicles from crossing or departing a section of roadway.

Barrier pair – A pair of phases within the same ring and between which cannot be displayed concurrently.

Base conditions – A set of specified standard conditions (e.g., good weather, good and dry pavement conditions, no disturbances, no impediments to traffic flow) that must be observed to analyze or predict operations that do not match.

Base length – The distance between the points in a weaving segment where the edges of the travel lanes of the merging and diverging roadways converge.

Base saturation flow rate – The saturation flow rate for the base conditions.

Baseline uniform delay – The average uniform delay when there is no initial queue.

Basic freeway segment – A length of freeway facility whose characteristics and operations are unaffected by weaving, diverging, or merging.

Bicycle – A vehicle with two wheels or less, propelled by human power, and usually ridden by one person.

Bicycle facility – A road, path, or way specifically designated for bicycle travel, whether exclusively or with other vehicles or pedestrians.

Bicycle lane – A portion of a roadway designated by striping, signing, and pavement markings for the preferential or exclusive use of bicycles.

Bicycle mode – A travel mode in which a motorized bicycle is used on a roadway or pathway.

Bicycle path – A bikeway physically separated from motorized traffic by an open space or barrier, either within the highway right-of-way or within an independent right of way.

Bicycle speed – The riding speed of bicycles in miles per hour or feet per second.

AR0074046

Bicycle track – A one-way bicycle facility separated from motor vehicle traffic and the sidewalk by low curbs.

Body ellipse – The practical minimum area for standing pedestrians.

Bottleneck – A system element on which demand exceeds capacity.

Boundary intersection – An intersection defining the endpoint of an urban street segment.

Breakdown – The transition from uncongested to congested conditions, typically observed as a speed drop accompanied by queue formation.

Breakdown flow – The flow at which operations transition from uncongested to congested.

Buffer width – The distance between the outside edge of the paved roadway (or face of curb, if present) and the inside edge of the sidewalk.

Bus – A self-propelled, rubber-tired, motor vehicle designed to carry a substantial number of passengers (at least 15) and commercially operated on streets and highways.

Bus lane – A highway or street lane reserved, primarily for buses during specified periods. It may be used by other traffic under certain circumstances, such as making a right or left turn, or by taxis, motorcycles, or carpools that meet the requirements of the jurisdiction's traffic laws.

Bus route – A fixed path or route operated by motor transit vehicles that follow fixed routes and schedules along roadways.

Bus shelter – A structure with a roof and (typically) three enclosed sides that protects waiting transit passengers from wind, rain, and sun.

Bus stop – A designated area along a street where one or more buses can simultaneously stop to load and unload passengers. It can be a curb lane (bus stop totally or partially in the travel lane) or off-line (bus stop out of the travel lane).

Busway – A right-of-way restricted to buses by a physical separation from other traffic lanes.

Bypass lane – A lane provided at a roundabout that allows a particular traffic movement to bypass the facility. Typically a one-way roadway.

Calibration – The process by which the analyst modifies model parameters so that the model estimates best reproduce field-measured local traffic conditions.

Call – A registration of a demand for right-of-way by vehicles or pedestrians to a controller.

Capacity – The maximum sustainable hourly flow rate at which persons or vehicles reasonably can be expected to traverse a point or a uniform section of a lane or roadway during a given time period under prevailing roadway, environmental, traffic and control conditions.

Case – See *Scenario*.

Central area pricing – An area-wide implementation of congestion pricing that imposes tolls for vehicles both entering and traveling within a central area's road network during certain hours of certain days.

Central business district (CBD) – An area with characteristics including many travel rights-of-way, frequent parking maneuvers (vehicle or pedestrian), taxi and bus activity, small-radius turns, inefficient use of curb lanes, high pedestrian activity, dense population, and multiblock curb cuts.

Change interval – See *yellow change interval*.

Circulating flow – The flow circulating with the entry flow on the subject approach to a roundabout (i.e., the flow passing to the left of the splitter island nose to the subject entry).

Circulation area – 1. The portion of a sidewalk intended to be used for pedestrian movement. 2. The average area available to each person using a pedestrian facility.

Circulation time-space – The total available time-space minus the time-space occupied by pedestrians waiting to cross a crosswalk.

Circulatory roadway – The curved one-lane section of a roundabout that requires other vehicles entering the roadway to yield.

Class I two-lane highways – Highways where motorists expect to travel at relatively high speeds, such as major intercity routes, primary connectors of major traffic generators, daily commuter routes, or major links in state or national highway networks.

Class II two-lane highways – Highways where motorists do not necessarily expect to travel at high speeds, such as access routes to Class I facilities, scenic or recreational routes, or routes passing through rugged terrain.

AR0074047

Class III two-lane highways – Highways serving moderately developed areas or portions of a Class I or Class II highway that pass through small towns or developed recreational areas.

Clearance interval – See yellow change interval.

Clearance lost time – The time at the end of a signal phase during which the movements served by that phase are not used by any traffic because drivers decelerate and stop or respond to the presentation of a yellow indication.

Clearance time – 1. The interval when a lane is ready to depart during which a trailing vehicle is not available for service at a stop line, consisting of the sum of startup delay and the unit extension. 2. See clearance lost time and clearance interval.

Climbing lane – A passing lane added to an upgrade to allow traffic to pass heavy vehicles who are operating at reduced speeds.

Cloverleaf interchange – An interchange with four loop ramps and four diagonal ramps, with no traffic control on either crossing roadway.

Collector street – A urban street providing land access and traffic circulation within residential, commercial, and industrial areas.

Collector-distributor road (C-D road) – A continuous roadway without local access provided parallel to a freeway to provide one or more interchanges for the purpose of removing weaving, speed change, or other operational changes and delays from the mainline.

Common green time – The period of time when the phases at the two intersections of an arterial have the right-of-way to permit a given platoon to proceed from origin to destination movement.

Complete trip – A vehicle that enters the network during the analysis period; the analysis period is long enough that the vehicle can reach its destination before the end of the analysis period.

Composite grade – A series of adjacent grades along a highway that can approach, but not exceed, the critical length of grade for a single upgrade.

Compressed diamond interchange – A diamond interchange with a separation of 400 to 800 ft between the two intersections.

Computational engine – A software implementation of one or more models

Conflict – The crossing, merging, or diverging of two traffic streams at an intersection.

Conflicting approach – An approach whose vehicles in the intersection must yield to the left-turn or through movement of the subject approach.

Conflicting flow rate – The total flow rate in vehicles per hour of a specific movement that impedes the subject movement.

Conflicting movements – Vehicular, pedestrian, or bicycle streams that seek to occupy the same space at the same time.

Congestion – 1. Low-flow, high-occupancy traffic operations that arise when demand approaches or exceeds a system or element's capacity. 2. A difference between the highway system performance expected by users and how the system actually performs. For example, an observation that more vehicles were queued than normal, or that delay was greater than normal, on a freeway or in a large metropolitan area.

Congestion pricing – The practice of charging tolls for use of all or part of a facility at levels that vary according to the severity of congestion.

Continuous flow interchange – A diamond interchange that allows left-turning traffic from the arterial to be uncontrolled or crossed by the left side of the roadway in advance of the interchange, between the crossover and the ramp terminal. The left-turning traffic travels in its own roadway between the approaching through arterial traffic (on the right) and right-turning traffic from the arterial (on the left). Both left-turning traffic streams merge at the near ramp terminal and then left-turn to the off-ramp at the far ramp terminal, without conflicting with opposing through arterial traffic. Also known as displaced left-turn interchange.

Control condition – The traffic controls and regulations invoked for a sequence of adjacent highways, including the type, phasing, and timing of traffic signals and stops, interactive and fixed controls, and similar measures.

Control delay – Delay associated with vehicles slowing in the queue on an intersection approach, the time spent stopped on an intersection approach, the time spent accelerating to the desired speed.

AR0074048

Controller – Hardware or software control device that interrupts traffic flow (e.g., a traffic signal, stop sign, or HOV ramp signal).

Conventional diamond interchange – A diamond interchange with a ramp terminal spacing of 300 ft or more between the two intersections.

Coordinated actuated control – A variation of semiactuated operation that uses the controller's force-off settings to establish the noncoordinated phases associated with the ring structure such that the coordinated phases are served at the start of green and progression for the major movements is maintained.

Corridor – A set of parallel transportation facilities, for example a freeway and an arterial street.

Crawl speed – The maximum sustained speed that can be maintained by a specified type of vehicle on a constant upgrade of a given percent.

Critical density – The density at which capacity occurs for a given facility.

Critical headway – The minimum headway in the stream of traffic or subset that will allow the entry of one additional vehicle.

Critical lane groups – The lane groups that have the highest flow ratio for a given signal group.

Critical phase – One (or more) of a set of phases that occur in sequence and whose combined flow ratios establish the longest cycle length.

Critical segment – The segment that will break down first, given that all other roadway and control conditions do not change, including the spatial configuration and demand on each component segment.

Critical speed – The speed at which capacity occurs on a segment.

Critical volume-to-capacity ratio – The proportion of available capacity required to move the vehicles in critical lane groups.

Cross flow – A pedestrian flow that is approximately perpendicular to and crosses another pedestrian flow or vehicular flow. The opposite of the cross-flow movement.

Crossing time – The curb-to-curb roadway distance divided by the pedestrian walking speed used in the Highway Capacity Manual. (Same as Walk.)

Crosswalk – A pedestrian facility.

Crosswalk occupancy time – The product of the pedestrian walking time and the number of pedestrians using a crosswalk during one signal cycle.

Curb extension – An extension of the sidewalk to the edge of the travel or parking lane.

Cycle – A complete sequence of signal indications.

Cycle failure – A condition where one or more queued vehicles are not able to depart due to insufficient capacity during the cycle in which they arrive.

Cycle length – The time elapsed between the initiation of two successive sequences of a given movement for coordinated signals; this is measured by using the coordinated phase given for a cycle.

Cyclic spillback – A queue for which the downstream boundary intersection is signalized and is operating such that the upstream intersection is blocked as a result of queue growth during the red indication.

D

D-Factor – The proportion of traffic traveling in the peak direction at a point or segment of roadway during the peak hour.

Daily service volume – The maximum total daily volume in both directions that can be sustained for a given segment without violating the criteria for LOS E in the peak direction for the worst 15 or 30 min of the peak hour under prevailing roadway, traffic, and control conditions.

Deceleration lane – A paved nonconventional lane, including paved area, allowing vehicles leaving the through traffic lane of the roadway to decelerate.

Default value – A representative value that can be used in the absence of site-specific data.

Degree of conflict case – For all-way stop-controlled intersections, a particular combination of vehicle presence in the approaches with respect to the subject approach.

Degree of saturation – See demand to capacity ratio.

Delay – Additional travel time experienced by a driver, passenger, bicyclist, or pedestrian beyond that required to make the desired speed.

Delayed passing maneuver – The total time of an average bicyclist to make a passing

AR0074049

movement immediately downstream of the presence of bicycle or other path users ahead of the vehicle in the same direction and a path user in the opposite direction.

Demand – The number of vehicles or other roadway users desiring to move past a given point on a system element during a specified time period, typically 1 hour or 15 min.

Demand flow rate – The number of vehicles or other roadway users desiring to move past a given point on a system element during the analysis period, converted to an hourly rate. When expressed as a rate for 15 min, this flow rate is based on a traffic count between 15 and 30 min after the start of the analysis period. This distinction is important for events made during congested periods because the count of vehicles departing the system element will produce a demand flow rate that is lower than the true rate.

Demand starvation – A condition occurring when a signalized approach has adequate capacity but a significant portion of the traffic demand is held upstream and prevented from the capacity provided because of the signalization pattern.

Demand volume – The number of vehicles that desire to use a facility. Under nonoversaturated conditions demand volume is equal to the observed volume.

Demand-to-capacity ratio – The ratio of demand volume to capacity for a system element.

Density – The number of vehicles occupying a given length of a lane or roadway at a particular instant. See also *volume/density*.

Departure headway – The average time between departures of successive vehicles on a given approach at a signalized or stop-sign controlled intersection.

Descriptive model – A model that shows how events unfold given a time plot describes how the system being modeled will behave.

Design hour – An hour with a traffic volume that represents a reasonable value for designing the geometric and control elements of a facility.

Design hour factor – The proportion of the AADT that occurs during the design hour analysis hour. See also *K factor*.

Design-level analysis – Any application of the HCM to establish the detailed physical features that will be built or modified.

facility to operate at a desired LOS or performance value.

Design speed – A speed used to design the horizontal and vertical alignments of a highway.

Detection zone – The portion of a signalized intersection approach where a vehicle can be detected by the signal controller (loop detector, video camera, image or other technology), resulting in the display of the green indication for the approach being extended.

Deterministic model – A mathematical model that is not subject to random processes. For a given set of inputs, the result from the model is the same with every application.

Deterministic queue delay – The component of control delay, in excess of the delay to all vehicles arriving during the analysis period when the demand flow rate exceeds the capacity of an approach, computed by approximating the vehicular inputs and outputs under the assumption of uniform arrivals.

Diamond interchange – An arterial interchange with a single-point diamond ramp terminal configuration in each highway quadrant and with two connections per quadrant.

Directional design hour volume – The traffic volume for the design hour in the peak directional flow.

Directional distribution – A characteristic of traffic that indicates how the peak hour volume in the direction of the peak 15 min of the peak hour. See also *D factor*.

Directional flow rate – The flow rate in a highway in one direction.

Directional segment – A length of two-lane highway in one travel direction with homogeneous cross sections and relatively constant demand volume and vehicle mix.

Directional split – See *D factor*.

Diverge – A movement in which a single stream of traffic separates into two streams without the aid of traffic control devices.

Diverge segment – See *merge/diverge segment*.

Diverging diamond interchange – A diamond interchange in which traffic on the arterial switches sides of the street at both of the ramp terminals, allowing left turns to merge to or made directly from opposing through or similar traffic.

AR0074050

Double-crossover interchange – See *diverging diamond interchange*.

Downstream – The direction of traffic flow.

Driver population factor – A parameter that accounts for driver characteristics that differ from base conditions and that influence traffic.

Dual entry – A right-of-way control (i.e., a roadway or ramp control) in which one pulse in each approach lane is served. Each pulse does not necessarily result in the vehicle being served; a pulse is served by the controller in a predetermined manner.

Duration of congestion – The amount of time that a congestion exists on the transportation system.

Dwell time – The time a bus or rail car is stopped to serve passengers. At a transit stop, dwell time includes time required to open and close doors while boarding and alighting passengers.

Dwell time variability – The distribution of dwell times at a stop because of fluctuations in passenger demand for boarding and alighting.

Dynamic traffic assignment model – A class of traffic assignment models that is based upon behavioral principles and that is designed to produce (e.g., maximize the level of service or desirability associated with a trip) that is precisely unproved over a sequence of time periods until the network reaches a state of equilibrium.

Effective available time-space – The available crosswalk time-space, adjusted to account for the effect of any pedestrians.

Effective green time – The time during which a given traffic movement or set of movements may proceed at the saturation flow rate. It is equal to the split time minus the lost time.

Effective red time – The time during which a given traffic movement or set of movements is not given the right-of-way. It is equal to the cycle length minus the effective green time.

Effective walk time – The time that a WALK indication is displayed to a crosswalk pedestrian. This time is the sum of the WALK indication time used by pedestrians to initiate their crossing.

Effective walkway width – The portion of a pedestrian facility's width that is usable for pedestrian circulation.

85th percentile speed – A speed value that is exceeded by 15% of the vehicles in a traffic stream.

Empirical model – A model that describes system performance and that is based on the statistical analysis of field data.

Entrance ramp – See *on ramp*.

Entry flow – The traffic flow entering a roundabout on the subject approach.

Environmental conditions – Conditions such as adverse weather, bright sunlight directly in drivers' eyes, and disruptions from traffic or pedestrians at a nearby driveway that may cause drivers to slow down and increase their spacing, resulting in a drop in a roadway's capacity.

Event – A specific occurrence of a vehicle or pedestrian arriving at a location.

Event-based model – A simulation model that advances from one event to the next, skipping over intervening points in time when no events occur.

Excess wait time – The average number of minutes that passengers must wait at a stop past the scheduled departure time.

Exclusive bus lane – A highway or street lane reserved for buses.

Exclusive off-street bicycle paths – Paths physically separated from highway traffic provided for the exclusive use of bicycles.

Exclusive turn lane – A designated left- or right-turn lane used only by vehicles making those turns.

Exit flow – The traffic flow leaving a roundabout to the subject leg.

Exit ramp – See *off ramp*.

Extent of congestion – The maximum physical length of the congestion on a transportation system at any one time.

Facility – A length of roadway, bicycle path, or pedestrian walkway composed of a connected series of points and sections.

Failure rate – The number of cycles in which all approaches and all available loading areas allocated to other buses.

Far-side stop – A transit stop where buses or other vehicles clear an intersection before stopping to serve passengers.

Fixed-object effective width – The sum of the physical width of a fixed object along a

AR0074051

walkway or sidewalk may functionally substitute space associated with the object and the width given in the description.

Fixed obstruction – A nonmovable object in a roadway, including light poles, signs, trees, permanent bridge rails, traffic barriers, and retaining walls.

Flared approach – At a two-way stop-controlled intersection, a shared right-turn lane that allows right-turning vehicles to maneuver in a manner that avoids other vehicles and encourages free turns.

Flow rate – The equivalent hourly rate at which vehicles or other roadway users pass over a given point or section of a lane or roadway during a given time interval less than 1 h, usually 15 min.

Flow ratio – The ratio of the actual flow rate to the saturation flow rate for a lane group at an intersection.

Follow-up headway – The time between the departure of one vehicle from the stop line and the departure of the next vehicle using the same initial queue position, under a condition of continuous queuing at the intersection.

Follower density – The number of followers per mile per lane; the following state is determined by comparing the gap with the following vehicle to the driver's desired gap.

Force-off – A point within a cycle where the actuated phase runs end regardless of continued demand. This results in a coordinated cycle ensure that the coordinated phases receive their assigned amount of green time.

Four-phase pattern – A type of operation at a freeway-ramp controlled intersection with individual approaches, which allows traffic from a given approach to enter the intersection together, in right-of-way pairs, with the approach to the next ramp terminal in turn.

Free flow – A flow state unaffected by upstream or downstream conditions.

Free flow speed – 1. The theoretical speed when the density and flow rate on a study segment are both zero. 2. The prevailing speed on freeways at flow rates between 0 and 1,000 passenger cars per hour per lane (pc/h/ln).

Freeway – A fully access-controlled, divided highway with a minimum of two lanes and for one-way traffic in each direction.

Freeway auxiliary lane – An additional lane on a freeway to connect an on-ramp and an off-ramp.

Freeway diverge segment – A freeway segment in which a single traffic stream divides to head two or more separate traffic streams.

Freeway facility – An extended length of freeway composed of one or more directly connected basic freeway, weaving, merge, and diverge segments.

Freeway facility capacity – The capacity of the total set of basic segments comprising a defined freeway facility.

Freeway merge segment – A freeway segment in which two or more traffic streams combine to form a single traffic stream.

Freeway section – A portion of a freeway facility with a constant demand and a constant number of lanes.

Freeway weaving segment – Freeway segment in which two or more traffic streams traveling in the same general direction cross paths along a significant length of freeway without the aid of traffic control devices (except for guide signs).

Full stop – The stopping of a vehicle for less than 1 min.

Fully actuated control – A type of operation in which vehicle detectors at each approach to the intersection control the sequence and length of every phase.

Furniture zone – The buffer area between the sidewalk and the curb and the area reserved for pedestrian travel, it may be used for landscaping, utilities, or pedestrian amenities.

Gap – The space or time between two vehicles, measured from the rear bumper of the second vehicle to the front bumper of the second vehicle. See also headway.

Gap acceptance – The process by which a driver accepts an available gap in traffic to perform a maneuver.

Gap out – At the end of actuated operation for a given phase when the phase terminates because of a lack of vehicle calls within the passage time.

General terrain – An extended length of highway containing a number of upgrades and downgrades where neither grade is

AR0074052

long enough to keep through traffic from significant impact on the operation of the exit ramp queue.

Generalized service volume table – A table containing for the base conditions estimates of the maximum volume a system element can carry at a specified level of service, given a default set of assumptions about the system element.

Geometric condition – The spatial characteristics of a facility, including approach grade, the number and width of lanes, turn bays, and parking lanes.

Geometric delay – Delay caused by the physical characteristics of the roadway, which force a driver to decrease speed below the desired cruise speed of the system element.

Gore area – The area located immediately between the lane edges of a ramp gore and the edge of the roadway at the theoretical point of ramp merge or diverge.

Green time – The duration of the green indication given movement at a signalized intersection.

Green time to cycle ratio – The ratio of the effective green time of a phase to the cycle length.

Growth factor – A percentage increase applied to current traffic demand to estimate future demands.

H

Hand conversion – The conversion of a vehicle from HCM customary units to metric units for international use through the application of rounding such as from 12 ft to 4 m. See also soft conversion.

Headway – The time between two successive vehicles as they pass a point on the roadway, measured from the same common feature of both vehicles (for example, the front axle or the front bumper).

Heavy vehicle – A vehicle with more than four tires touching the pavement during normal operation.

High-occupancy vehicle (HOV) – A vehicle with a defined minimum number of occupants (2+, 3+, etc., as determined by the agency), such as buses and carpools, which a lane is reserved for the use of.

Highway – A general term for denoting a public way for purposes of vehicular travel, including the entire area within the right-of-way.

Hindrance – Diversion and inconvenience to a bicyclist as a result of meeting, passing, or being overtaken by other pedestrians or users.

Holding area waiting time – The average time that pedestrians wait to cross the street in departure from the subject corner.

Hybrid models – Models that use both macro- and large network analysis that apply microscopic modeling to critical subsystems and the extension of macroscopic modeling to the remaining facilities.

I

Impedance – The reduction in the capacity of lower-rank movements caused by the presence of higher-rank movements at the two-way stop-controlled intersection.

Incident – Any occurrence on a roadway that impedes the natural flow of traffic.

Incident delay – The component of delay that results from an incident. Computed as the nonincident condition.

Incomplete trip – A vehicle trip that is unable to enter and exit successively the spatial domain of an analysis within the analysis period.

Incremental delay – Uniform delay plus any group control delay, accounting for delay due to the random arrival of vehicles, the fluctuations in queue and that occasionally exceed capacity (i.e., cycle failure) and delay due to perceived oversaturation during the analysis period.

Influence area – 1. The base length of a freeway weaving segment plus 500 ft upstream of the entry point to the weaving segment and 500 ft downstream of the exit point of the weaving segment. Entry and exit points are defined as the points where the appropriate edges of the merging and diverging lanes meet. 2. The acceleration lane(s) and Lanes 1 and 2 of the freeway mainline for a distance of 1,500 ft downstream of the merge point. 3. The deceleration lane(s) and Lanes 1 and 2 of the freeway for a distance of 1,500 ft upstream of the diverge point.

Initial queue – The internal demand at the beginning of an analysis period, either measured in the field or carried over from the computation of a previous analysis period.

Initial queue delay – The third term of the group control delay, accounting for delay due to residual queue ideal for the previous analysis period and present at the start of the current analysis period. This

AR0074053

delay results from the additional time required to clear the initial queue.

Input – The data required by a model.

Instantaneous acceleration – Acceleration at a point, calculated from the initial and final speeds of a vehicle at the beginning and end of a time step, assuming a constant acceleration during Δt.

Instantaneous speed – A speed determined from data for a single point or a vehicle at a time interval Δt, assuming a constant acceleration during Δt.

Intelligent transportation system (ITS) – Transportation technology that allows drivers and traffic control system operators to gather and use real-time information to improve mobility, reliability, or system control, or both.

Intensity of congestion – The amount of congestion experienced by users of a system.

Interchange – A system of interconnecting roadways providing for traffic movement between two or more highways that do not intersect at grade.

Interchange density – The average number of interchanges per mile, measured over the entire extent of the downstream from the midpoint of the weaving segment.

Interchange ramp terminal – A junction of a ramp with a surface street that provides connecting or exiting driveway.

Internal link – The segment between two signalized intersections or other ramp terminals.

Interrupted flow – Traffic flow on facilities characterized by traffic signals, stop signs, or other fixed features that periodically cause delay or interruption to the traffic stream.

Intersection delay – The total additional travel time experienced by drivers, passengers, or pedestrians as a result of control measures and movements with other items of the facility, divided by the volume departing from the corresponding cross section of the facility.

Interval – A period of time for which all traffic signal indications remain constant.

Isolated intersection – An intersection experiencing negligible influences from upstream or downstream intersections, where flow is effectively random over the cycle and without a dynamic platoon pattern evident in the cycle profile of arrivals.

Jam density – The maximum density that can be achieved on a segment. It occurs when speed is zero (i.e., when there is no movement of persons or vehicles).

K factor – The proportion of AADT that occurs during the peak hour. Also called design hour factor.

Lane 1 – The highway lane adjacent to the outside shoulder.

Lane 2 – The highway lane adjacent to and left of Lane 1.

Lane balance – A condition when the number of lanes leaving a diverge point is equal to the number of lanes approaching it, plus one.

Lane distribution – A percentage used when two or more lanes are available for traffic in a single direction and the volume distribution across those lanes, depending on factors such as regulation, traffic composition, speed, and volume, the number and location of access points, the origin–destination patterns of drivers, the geometric characteristics, and local driver habits.

Lane group – A lane or set of lanes designated for separate analyses.

Lane group delay – The control delay for a given lane group.

Lane utilization – The distribution of vehicles among lanes when two or more lanes are available for a movement. See also proportion using.

Lane width – The lateral distance between stripes for a given lane.

Lateral clearance – 1. The sum of left- and right-side clearance from the outside edge of travel lanes to fixed objects on urban streets or multilane highways. 2. The right-side clearance is the distance from the edge of the travel lane to fixed objects on a freeway.

Leg – A section of an at-grade intersection accommodating all approaching movements associated with one of the roads entering the intersection.

Level of service (LOS) – A qualitative classification of a performance measure or measures that characterizes quality of service, measured on an A–F scale, with LOS A representing the best operating conditions

AR0074054

from the traveler's perspective and LOS is the service.

Level of service score (LOS score) – A numerical output from a behavior perception model that typically indicates the average rating that travelers would give a transportation facility or service under a given set of conditions.

Level terrain – Any combination of grades and horizontal or vertical alignment that permits heavy vehicles to maintain the same speed as passenger cars. It usually contains short grades of no more than 2%.

Light rail mode – A transit mode operated by vehicles that receive power from overhead wires and that run on tracks that can be located at grade within street rights-of-way. See also *streetcar mode*.

Link – A length of roadway between two nodes or points.

Link length – The distance from the upstream boundary intersection to the downstream boundary intersection.

Load factor – The number of passengers occupying a transit vehicle divided by the number of seats on the vehicle.

Loading area – A curbside space where a single bus can stop to load and unload passengers. Bus stops include one or more loading areas.

Local street – A street that primarily serves as land-access treatment.

Local transit service – Transit service making regular stops along a street (typically every 0.2 mi or less).

Loop ramp – A ramp that a driving vehicle has to execute a left turn by turning a full circle. An example is a 360-degree left turn; training, a 270-degree left turn.

Lost time – The time during which the movement of a phase is not effectively using the approach or intersection. It is the sum of clearance lost time and start-up lost time.

M

Macroscopic model – A mathematical model that considers traffic conditions averaged over specified time intervals and specified segments of links without investigating individual vehicles in the traffic stream.

Mainline – The primary through roadway as distinct from ramps, auxiliary lanes, and collector–distributor roads.

Mainline output – The maximum number of vehicles that can serve a freeway mode, constrained by downstream bottlenecks or by merging traffic.

Major diverge area – A location where one freeway segment diverges to form two primary freeway segments with multiple lanes.

Major merge area – A location where two primary freeway segments, each with multiple lanes, merge to form a single freeway segment.

Major street – The street that is controlled by STOP signs at a two-way STOP-controlled intersection.

Major weaving segment – A weaving segment with at least three entry and exit legs, a total of two or more lanes.

Managed lanes – A limited number of lanes set aside within a freeway cross section where multiple operational strategies are utilized and in which vehicles are managed as needed for the purpose of achieving predefined performance objectives. Examples include priced lanes and special use lanes such as high-occupancy vehicle, express, freeway, or truck only lanes.

Max out – A type of actuated operation for a given phase where the phase terminates because it has reached the designated maximum green time for the phase.

Maximum green – The maximum amount of time that a green signal indication can be displayed in the presence of conflicting demand.

Maximum recall – A form of phase recall where the controller places a call on each phase for vehicle service on the phase. This results in the presence of the green indication for the maximum duration every cycle.

Maximum weaving length – The length at which weaving turbulence no longer has an impact on the capacity of the weaving segment.

Median – The area in the middle of a roadway separating opposing traffic flows.

Meeting – An encounter of bicycles or pedestrians moving in the opposite direction of the subject bicycle flow.

Merge – A maneuver in which two separate streams of traffic combine to form a single

AR0074055

streets without the aid of traffic signals or other right-of-way controls.

Merge segment – See freeway merge segment.

Mesoscopic model – A mathematical model for the macroscopic analysis of platoons of vehicles that employs relationships to describe how the platoons interact.

Microscopic model – A mathematical model that captures the movements of individual vehicles and their car-following, lane-change, and gap-acceptance decisions at small time intervals, usually 1 s or smaller.

Midblock stop – A transit stop located at a point away from intersections.

Minimum green – The least amount of time that a green signal indication will be displayed when a signal phase is activated.

Minimum recall – A form of phase recall where the controller places a continuous call to service the phase and then services the phase at the minimum green duration each cycle.

Minor movement – A vehicular flow in a specific directional entity (also an aggregation of movements that must yield to other movements).

Minor street – The street controlled by stop or yield signs at a two-way or all-way controlled intersection.

Mixed-traffic operation – Operation of a transit mode in lanes shared with other roadway users.

Mobility – The ability of people and goods to travel from place to place.

Mode – See *transit mode*.

Model – A procedure that uses one or more algorithms to produce a set of numerical outputs describing the operation of a segment or system, given a set of numerical inputs.

Model application – The physical configuration and operational constraints to which a traffic analysis tool is applied.

Mountainous terrain – Any combination of grades and horizontal and vertical alignment that causes heavy vehicles to operate at crawl speed for significant distances or at frequent intervals.

Move-up time – The time it takes a vehicle to move from a service position to the next position in a queue at a stop-controlled intersection.

Movement capacity – The capacity of a specific traffic stream at a fully controlled intersection approach, assuming that the traffic has exclusive use of a separate lane.

Movement groups – A categorization of traffic movements at a signalized intersection by predominant geometry. A separate movement group is established for each lane that has movements with one or more exclusive turns. Through plus right-turn and through plus left-turn movements are also considered exclusive as any turn movements that share a lane.

Multilane highway – A highway with 2 or more lanes for the exclusive use of traffic in each direction, with no control or partial control of access. It may have periodic crossings at grade but should not have traffic signals within 3 mi of each other.

Multilane roundabout – A roundabout with more than one lane on at least one entry and at least part of the circulatory roadway.

Multimodal – Being used by more than one travel mode.

Multimodal analysis – A type of HCM analysis where the LOS for each travel mode on a facility is evaluated simultaneously.

Multiple weaving segment – A portion of a freeway where more than one pair of merge and diverge areas create overlapping weaving movements between adjacent merge–diverge pairs.

Near-side stop – A transit stop located on the approach side of an intersection. Transit vehicles stop to serve passengers before crossing the intersection.

No-passing zone – A segment of a two-lane, two-way highway along which passing maneuvers are prohibited in one or both directions.

Node – The end point of a link. See *centroid*.

Nonlocal transit service – Transit service on routes with an operating strategy (such as service type, limited-stop, express, or express-only) that is not local service.

Nonweaving flow – The total flow rate in that weaving segment that is not involved in weaving movements.

Nonweaving movement – A traffic flow within a weaving segment that does not need to cross paths with another traffic flow while traversing the segment.

AR0074056

Normative model – A mathematical model that identifies a set of parameters providing the best system performance.

O

Off-line bus stop – See bus stop.

Off ramp – A ramp that accommodates diverging maneuvers.

Off-street path – See shared-use path; path.

Offset – The time that the reference phase begins (seconds) relative to the system master time zero.

On-line bus stop – See bus stop.

On-ramp – A ramp that accommodates merging maneuvers.

On-street transitway – A portion of a street right-of-way dedicated to one particular mode, physically separated from other traffic, and located in the median or adjacent to one side of the street.

One-sided weaving segment – A weaving segment in which all weaving maneuvers require more than two lane changes to be completed successfully.

Operations-level analysis – Any application of an analytical methodology where the user supplies all or nearly all required inputs to the procedure.

Opposing approach – At an all-way stop-controlled intersection, the approach approximately 180 degrees opposite the subject approach.

Opposing flow rate – The flow rate in the direction of travel opposite to the direction under analysis.

Outputs – The performance measures produced by a model.

Overflow queue – Queued vehicles left over from a given phase at a signalized intersection.

Oversaturated flow – Traffic flow where at the arrival flow rate exceeds the capacity at a point or segment, or a queue created from a prior breakdown of a facility has not yet dissipated, or traffic flow is affected by downstream conditions.

P

Partial cloverleaf interchange (parclo) – An interchange with ramps in fewer than four quadrants and two to four diagonal ramps with major turning movements less desirable (sometimes by signalization and crossings).

Partial diamond interchange – A diamond interchange with fewer than four ramps, so that not all of the freeway-street crossover movements are served.

Partial stop – A situation where a vehicle slows or approaches the back of a queue but does not come to a full stop.

Passage time – The maximum amount of time one vehicle actuation can extend the green interval beyond the point it is displayed. This is input for each actuated signal phase. Also referred to as vehicle interval, unit extension, interval extension, or unit extension.

Passenger-car equivalent – The number of passenger cars that will result in the same operational conditions as a single heavy vehicle of a particular type under specified roadway, traffic, and control conditions.

Passenger load factor – See *load factor*.

Passenger trip length – The average distance traveled by a passenger on board a transit vehicle.

Passing lane – A lane added to improve passing opportunities in one direction of travel on a two-lane, two-direction highway.

Passing sight distance – The length of highway required to complete normal passing maneuvers in which the passing driver can determine that he or she can pass a potentially conflicting vehicle ahead before regaining the normal lane.

Passive priority – A form of traffic signal priority that is retrieved, such as the setting of a street's signal progression to favor buses.

Pavement condition rating – A measure of the road surface in terms of ride quality and surface defects.

Peak hour – The hour of the day (usually the one hour with the highest volume) during the analysis hour divided by the peak 15-minute flow rate within the analysis hour; a measure of traffic demand fluctuation within the analysis hour.

Pedestrian – An individual traveling on foot.

Pedestrian clearance interval – Time provided for an inspection when departure from the curb during the WALK indication to reach the opposite curb for the next phase.

AR0074057

Pedestrian crosswalk – A connection between pedestrian facilities across a roadway used by automobiles, bicycles, and buses (or rails). Crosswalks can be marked or unmarked.

Pedestrian density – The number of pedestrians per unit area within a walkway or queuing area.

Pedestrian flow rate – The number of pedestrians passing a point per unit of time during a sub-hourly time period.

Pedestrian mode – A travel mode under which a journey or part of a journey is made on foot along a roadway or pedestrian facility.

Pedestrian overpass – A grade separated pedestrian facility over roadways, railroad tracks, or other topographic features.

Pedestrian phase – A long green interval that serves multiple functions, including pedestrian circulation, special events, and parking.

Pedestrian queuing area – A place where pedestrians stand temporarily while waiting to cross a road, such as the corners of a signalized intersection.

Pedestrian recall – A type of phase control where the controller places continuous calls for pedestrian service at the beginning of each cycle. This services the phase for at least an amount of time equal to its walk and pedestrian clearance intervals (longer if vehicle detection is not covered).

Pedestrian service time – The elapsed time starting with the full pedestrian signal display from the curb or the last pedestrian's arrival at the far side of the roadway.

Pedestrian space – The average area provided for pedestrians in a moving pedestrian stream or pedestrian queue.

Pedestrian start-up time – The time for a platoon of pedestrians to get under way, following the beginning of the walk interval.

Pedestrian street – A street dedicated to pedestrian use with full or partial access.

Pedestrian underpass – A grade separated pedestrian facility under roadways, railroad tracks, high-speed roadways, or other topographic features.

Pedestrian walkway – A pedestrian facility similar to a sidewalk in concept but not adjacent to a road. Examples include the interiors of automobile malls.

Percent free-flow speed – The average travel speed under the free-flow speed.

Percent time-spent-following – The average percent of total travel time that vehicles must travel in platoons behind slower vehicles because of inability to pass on a two-lane highway.

Performance measure – A quantitative or qualitative characterization of some aspect of the service provided to a certain road user group.

Permitted plus protected – A separate left-turn protection that displays for permitted period before the protected phase.

Permitted turn – A left-turn operation at a signalized intersection that is made by a vehicle, usually during the cycle in which the vehicle does not have the right-of-way.

Person capacity – The maximum number of persons who can pass a given point during a specified period under prevailing conditions.

Phase – The part of the signal cycle allocated to any combination of traffic movements receiving the right-of-way, simultaneously, during one or more intervals. A phase includes the green, yellow change, and red clearance intervals.

Phase pair – See barrier pair.

Phase pattern – The combination of right-of-way assigned to traffic streams at a multiway STOP-controlled intersection.

Phase recall – A call made by the controller for a specified phase each time the controller is servicing a conflicting phase.

Phase sequence – 1. The sequence of service provided to each of the movements. 2. A description of the order in which the left-turn movements are served relative to the through movements.

Planning-level analysis – An application of the HCM generally directed toward broad policy questions, initial project identification, and assessing a large number of locations or corridors (typically less detailed than operations-level analysis and relative to before-and-after monitoring). Nearly all inputs to the analysis may be default values.

Platoon – A group of vehicles or pedestrians traveling together as a group, either voluntarily or involuntarily because of signal control, roadway features, or other factors.

Platoon ratio – A description of the quality of signal progression applied in the demand flow rate equation. Computed by dividing the average demand flow rate

AR0074058

Point – A point along a facility where (a) conflicting traffic streams cross, merge, or diverge; (b) a single traffic stream is regulated by a traffic control device; or (c) there is a significant change in the segment capacity (e.g., number of lanes added or removed, or a significant upgrade start or end of a ramp influence area).

Potential capacity – The capacity of a specific movement at a STOP-controlled intersection approach, determined that it is unimpeded by pedestrians or higher-rank movements and not exclusive use of a separate lane.

Precision – The closeness of the interval surrounding a measured quantity.

Preliminary engineering, level analysis – An HCM application conducted to support planning-oriented or initial conceptual design concepts and scope when alternatives analyses are performed, or to assess proposed system-wide policies. Many of the inputs to the analysis will be simulated.

Prepositioning – A deliberate driver choice of lane or lane group at an intersection in anticipation of a turn or a downstream intersection.

Pretimed control – A signal control in which the cycle length, phase plan, and phase times are preset to repeat continuously.

Prevailing conditions – The geometric, traffic, control, and environmental conditions during the analysis period.

Progression – The act of vehicles controlled by successive green indications in accordance with a time–distance pattern to permit continuous operation of groups of vehicles at a designated speed at a series of signals.

Protected plus permitted – Compound left-turn operation at a signalized intersection that displays the protected phase before the opposing phase.

Protected turn – The left or right turns at a signalized intersection that are made by a vehicle during a time in the cycle when the vehicle has the right-of-way.

Q

Quality of service – A description of how well a transportation facility or service operates from a traveler's perspective.

Quantity of service – A measure of the utilization of a transportation system.

Queue – A line of vehicles, bicycles, or pedestrians waiting to be served due to traffic control, a bottleneck, or other causes.

Queue delay – 1. The amount of time that a vehicle spends in a queued state. 2. When computed from vehicle trajectories, it is the accumulated time-step delay over all time steps in which the vehicle is in a queue.

Queue discharge flow – A traffic flow that has passed through the downstream bottleneck, is moving at the maximum speed of the freeway.

Queue jump – A short median section often shared with a right-turn lane in combination with an advance green indication for the lane that allows buses to move past a queue of cars at a signal.

Queue length – The distance between the upstream and downstream ends of the queue.

Queue spillback – A condition where the back of a queue extends beyond the available storage length, resulting in potential interference with upstream traffic movements.

Queue storage ratio – The maximum back of queue as a proportion of the available storage on the subject lane or link.

Queued state – A condition when a vehicle is within one car length (20 ft) of a stopped vehicle and is itself in a stopped state (i.e., is slowing to less than 5 mi/h).

R

Ramp – A dedicated roadway providing a connection between two other roadways, at least one of the roadways a ramp connects is typically a high-speed facility such as a freeway, multilane highway, or C-D roadway.

Ramp–freeway junction – The point of connection between a ramp and a high-speed facility such as a freeway, multilane highway, or C-D roadway.

Ramp meter – A traffic signal that controls the entry of vehicles from a ramp onto a limited-access facility; the signal displays one or two of the following: red, green, or green flash.

Ramp roadway – See ramp.

Ramp–street junction – See ramp–surface street junction.

AR0074059

Rank – The function by which all vehicles in conflicting traffic streams at a two-way STOP-controlled intersection.

Reasonable expectancy – The concept that the stated capacity for a given system element is one that can be achieved repeatedly during peak periods, rather than being the absolute maximum flow rate that could be observed.

Receiving lanes – Lanes departing an intersection.

Recreational vehicle – A motor vehicle, primarily operated by a private individual, for transporting recreational equipment or camping. Examples include campers, motor homes, and vehicles towing boat trailers.

Red clearance interval – A brief period of time following the yellow indication during which the signal heads associated with the ring, phase, and all conflicting phases display a red indication.

Red time – The period in the signal cycle during which, for a given phase or lane group, the signal is red.

Recovery delay – Delay experienced by a heavy vehicle or bus stop when they must wait for a gap in traffic before reentering the travel lane.

Reference phase – One of the two coordinated phases (see Phase Sets).

Regression model – A model that uses field or simulated data to develop statistically derived relationships between particular model inputs and performance measures, such as capacity and delay.

Residual queue – The number of vehicles at the end of the analysis period resulting from oversaturated conditions (i.e., demand exceeds capacity).

Rest-in-walk mode – A signal controller setting in which the phase will show the walk at only its first actuation. Once the walk is shown, it will not be shown again until a call is registered, the phase is shown, and the walk time has elapsed. Also known as rest-in-walk, no-pedestrian.

Restrictive median – A median (see median), raised or other physical device that prevents or discourages vehicles from crossing the opposing travel lanes.

Right-turn-on-red – The ability to make a right turn at a signalized intersection when a red indication is displayed, after stopping and only when no conflicting vehicular or pedestrian traffic is present.

Ring – A set of phases operating in sequence.

Roadside obstruction – An object or barrier along or adjacent to the roadside or median that affects traffic flow, whether vertical (e.g., curb, retaining wall, or bridge abutment), lateral (e.g., guardrail), or both (e.g., bridge pier).

Roadway – That portion of a highway improved, designed, or ordinarily used for vehicular travel and parking lanes but exclusive of the sidewalk, berm, or shoulder even though such sidewalk, berm, or shoulder is used by persons riding bicycles or other human-powered vehicles.

Roadway characteristic – A geometric characteristic of a street or highway, including the type of facility, number and width of lanes (by direction), shoulder width and lateral clearances, design speed and horizontal and vertical alignments.

Rolling terrain – Any combination of grades and horizontal or vertical alignment that occupy heavy vehicles to reduce their speed substantially below that of passenger cars but that does not cause heavy vehicles to operate at crawl speeds for any significant length of time or at frequent intervals.

Roundabout – An intersection with a perpendicularly circular shape, characterized by yield-at-entry and circulation around a central island.

Rubbernecking – The slowing of nonvehicle observers' traffic in close.

Running speed – See average running speed.

Running time – The time that a vehicle traverses a length of roadway excluding any delay related to traffic control devices.

Rural – An area with widely scattered development and a low density of housing and nonfarm businesses.

Saturation flow rate – The equivalent hourly rate at which persons or vehicles can traverse a point or uniform section of an approach during 60 minutes of green time, assuming that the green is never terminated and that there are always vehicles in queue. Also known as saturation flow.

Saturated flow – A traffic flow condition in which the number of vehicles approaching a point is greater than the number that can pass through the point during the green interval, so that some vehicles must wait through more than one cycle.

Saturated two-way – A signalized intersection approach where the average queue storage ratio (see queue storage ratio) for the left-turn lane(s) exceeds 1.0 and the left-turn lane(s) is not adequately protected.

Saturation headway – The average headway between vehicles crossing a stop line of a signalized approach, computed for the queued vehicles after the first four vehicles in the queue and ending with the last vehicle in the queue that exists before the intersection is cleared of all queued vehicles.

Saturation headway adjustment period – The time between the start of the green interval and the point at which the saturation headway is reached.

AR0074060

pedestrian crosswalk or bicycle crossing.

Scenario – See *analysis scenario*.

Segment – 1. For interrupted-flow facilities: a length of lane and its boundary points. 2. For uninterrupted-flow facilities: a portion of a facility between two points.

Segment delay – 1. The delay experienced by a vehicle while traveling through a segment, usually including traffic delay, incident delay, control delay, and geometric delay. 2. When calculated from cubic flow rates, the time actually taken to traverse a segment minus the time it would take to traverse the segment at the target speed. The segment delay for any time step is equal to the total of the applicable delays accumulated over all time steps in which a vehicle is present on the segment minus the segment delay for that vehicle.

Segment initialization – The process of determining the appropriate number of vehicles on each segment. A precursor to estimating the number of vehicles on each freeway segment for each time step in a non-oversaturated condition.

Semiactuated control – A signal control in which some approaches (typically on the minor street) have detectors and some of the approaches (typically on the major street) have no detectors.

Sensitivity analysis – A technique for exploring how model output changes in response to changes in model inputs, implemented by varying one input at a time over its reasonable range while holding all other inputs constant.

Service flow rate – The maximum hourly rate of flow that can be maintained in a given segment under prevailing roadway, traffic, and control conditions without violating the criteria for LOS *x*.

Service measure – A performance measure used to define LOS for a transportation system element.

Service lane – A lateral way with controlled intersections. The departure roadway mirrors the arrival roadway.

Service volume – The maximum hourly directional flow rate that can be sustained in a given segment without violating the criteria for LOS *x* during the worst 15 min of the hour (peak) with the highest density under prevailing roadway, traffic, and control conditions.

Shared lane – 1. A lane shared by more than one movement. 2. A bicycle facility where bicyclists share a travel lane with motorized vehicular traffic.

Shared-lane capacity – The capacity of a lane at an intersection that is shared by two or more movements.

Shared pedestrian–bicycle path – A path physically separated from highway traffic for the use of pedestrians, bicyclists, runners, in-line skaters, and other nonmotorized users.

Shock wave – A change in the uniformity of traffic conditions. For example, a shock wave is generated when the signal turns green, and it moves upstream as vehicles accelerate out of the queue, slow down. A shock wave is also generated when the signal turns green, and it moves downstream as the first set of vehicles discharge from the signal.

Short length – The distance within a weaving segment over which lane changing is not prohibited or discouraged by markings.

Shoulder – A portion of the roadway or its vertical extensions with the traveled way for accommodation of stopped vehicles, emergency use, and lateral support of the subbase, base, and surface courses.

Shoulder bikeway – A bicycle facility where bicyclists ride on the paved shoulder, separated by striping from motor vehicle traffic, for travel along a roadway.

Shoulder bypass lane – A portion of the paved shoulder opposite the minor road at a three-leg intersection, marked as a lane for through traffic to bypass vehicles that are slowing or stopped to make a left turn.

Shy distance – The buffer that pedestrians give themselves to avoid the potentially stopping of the cars, bushes, against a building face, or getting too close to pedestrians standing under awnings or window shopping.

Side street – See *minor road*.

Sidepath – A shared pedestrian–bicycle path located parallel and in proximity to a roadway.

Sidewalk – A pedestrian facility located parallel and in proximity to a roadway.

Simple weaving segment – A weaving segment formed by a single merge point followed by a single diverge point.

Simultaneous gap out – A control feature of actuated control by which a phase is not terminated by a maximum green interval but is terminated only when adequate gaps in traffic flow are detected on all conflicting approaches.

AR0074061

Single-entry – A movement (from a multilane approach) in which a portion of the vehicles in the lane(s) designated for the movement are required to enter a lane containing through traffic.

Single-point urban interchange – A diamond interchange for which all the ramp movements enter a single signalized intersection.

Single-stage gap acceptance – A condition where no more than one gap in the major-street traffic stream is available for minor-street drivers to enter, so that minor-street drivers must evaluate gaps in both major-street directions simultaneously.

Sketch planning tools – Tools that provide general order-of-magnitude estimates of travel demand and transportation system performance to help support high-level system improvement alternatives.

Soft conversion – The conversion of a value from U.S. customary units to metric units (or vice versa) through the application of a conversion factor, such as multiplying 12 ft by 0.305 m/ft, resulting in 3.65 m. See also *hard conversion*.

Spare – See *protected capacity*.

Space gap – See *gap*.

Space mean speed – An average speed based on the average travel time of vehicles to traverse a length of roadway.

Spacing – The distance between the same vehicle features (e.g., front axles) of two consecutive vehicles in a traffic lane, measured from the same common feature of the vehicles (e.g., rear axle, front bumper, or front bumper).

Spatial stop rate – The rate of stop rate per facility length.

Spatial variability – Variability in the observed values, such as the percentage of trucks in the traffic stream, from one location to another – within an area or from one area to another.

Special events – Unusual high-demand events that occur at known times and relatively infrequently, resulting in traffic flow patterns that vary substantially from the typical situation.

Specific grade – A single grade or a roadway segment or a complex roadway segment expressed as a percentage.

Speed – A rate of motion expressed as distance per unit of time.

Speed harmonization – A technique to reduce the shock waves that typically occur when traffic approaching a slowdown or a bottleneck is forced to decelerate, through the use of variable speed limits or advisory speed signs.

Split/Lack – See *queue spillback*.

Spillover – A condition occurring when a pedestrian queue at a corner spills over to the crosswalk, forcing pedestrians (e.g., by creating gaps in the street) to travel at their desired speed.

Split – The portion of the cycle length allocated to each phase or interval that may occur. In actuated control systems, split is the time in the cycle allocated to a phase—the sum of the green, yellow change, and red clearance intervals for a phase.

Split-diamond interchange – Diamond interchanges in which freeway entrance and exit ramps are separated at the street level, creating four intersections.

Stairway – A pedestrian facility that provides a grade change using a series of steps and landings.

Standee – A passenger standing in a transit vehicle.

Start-up lost time – The additional time consumed by the first few vehicles in a queue (above saturation flow headway) in excess of the normal headway because of the need to react to the initial display of the green phase and to accelerate.

Static flow model – A mathematical model in which the traffic flow rate and origin–destination volumes are constant.

Stochastic model – A mathematical model that uses random variables or probabilistic components to represent at least one parameter.

Stop rate – The ratio of total stops divided by the number of vehicles served.

Stop spacing – See *average stop spacing*.

Stopped delay – The amount of time that a vehicle is stopped. When calculated from vehicle trajectories, it equals the time the vehicle is in the stopped state. Time-step delays are calculated over all time steps in which the vehicle speed is in the stopped state (or at/below the stopped delay speed threshold).

Stopped state – A condition where a vehicle is traveling at less than 5 mi/h.

Storage length – The length of turn lane available for storing queued vehicles.

Street – See *roadway*.

Street corner – The area encompassed within the intersection of two sidewalks.

AR0074062

Streetcar mode – A transit mode operated by vehicles that receive power from overhead wires and run on tracks. Compared with rapid rail, streetcars are generally shorter and narrower, are more likely to have unreserved fare collection, make more frequent stops, and are more likely to operate in mixed traffic.

Study period – See analysis period.

Subject approach – The approach under the study at a two-way and a one-way stop-controlled intersection.

Suburban street – A street with low-density driveway access on the periphery of an urban area.

Sustained spillback – A result of oversaturation, where queuing does not dissipate at the end of each cycle but remains present until the downstream capacity is increased or the upstream demand is reduced.

System – All the transportation facilities and modes within a particular region.

System elements – Components of a transportation system, including spirals, segments, facilities, terminals, and areas.

Taper area – An area characterized by a reduction or increase in pavement width to direct traffic.

Target speed – In a simulation tool, the speed at which a driver would prefer to travel, a difference from the free-flow speed in that most simulation tools apply a "driver aggressiveness" factor to the free-flow speed to determine a target speed.

Temporal variability – Variability in measured values, such as hourly traffic volumes. Traffic varies from day to day, month to month, and at a given location.

Terrain – See grade and terrain.

Three-level diamond interchange – A diamond interchange with two grade-separated levels of roadway facilities providing continuous through movements.

Through vehicles – All vehicles passing directly through a street segment and not turning.

Tight urban diamond interchange – A diamond interchange with a separation of less than 600 ft between the two intersections.

Time interval – See analysis period.

Time interval scale factor – The ratio of the total durable variance source to total facility variance.

Time mean speed – The average speed of vehicles at a point or over a segment of a highway.

Time gap – See gap.

Time space domain – A specification of the freeway corridor (or subject portion of the facility) and an identification of the time intervals for which the analysis is to be conducted.

Time step delay – The length of a time step minus the time it would have taken a vehicle to cover the distance traveled in the step at the target speed.

Time varying flow model – A simulator model in which flows change with time.

Tool – See traffic analysis tool.

Total lateral clearance (TLC) – The sum of the right-side and left-side lateral clearances at a single cross section of a highway.

Total lost time – See lost time.

Total ramp density – The average number of on-ramp, off-ramp, major merge, and major diverge segments per mile. It applies to a 10-segment freeway facility. See also boundary and influence area at the upstream end of the study segment.

Traffic analysis tool – A software product used for traffic analysis that includes, at a minimum, a computational engine and a user interface.

Traffic condition – A characteristic of traffic flow, its typical distributions of vehicle types in the traffic stream, directional distribution of traffic, time-of-day distribution of traffic, and type of driver population on a given facility.

Traffic control device – A sign, signal, marking, or other device used to regulate, warn, or guide traffic.

Traffic delay – The component of delay that can be attributed to the interaction of vehicles and causes drivers to reduce speed below the free-flow speed.

Traffic incidents – Occurrences, such as crashes, stalled cars, and debris in the roadway, that do not occur every day. These incidents reduce roadway capacity and create variation in day-to-day travel times along the roadway.

Traffic pressure – The display of aggressive driving behaviors by a large number of drivers during high-demand traffic.

AR0074063

conditions. Under saturated conditions, a large number of drivers accept smaller headways than they would be comfortable with if they would prefer different accelerations.

Traffic signal delay – Delay experienced by a bus that arrives at a bus stop during the green indication, serves its passengers during portions of the green and red intervals, and then must wait for the traffic signal to turn green again before proceeding. See also control delay.

Traffic signal optimization tool – A tool primarily designed to develop optimal signal phasing and timing plans for isolated signalized intersections, arterials, networks, or signal networks.

Transit frequency – The number of transit vehicles that stop at or travel past a point during a specified time period.

Transit mode – A travel mode involving vehicles traveling between stations, terminals, and street networks along the roadway to pick up and discharge passengers.

Transit reliability – A measure of the time performance and the predictability of roadway between successive transit vehicles at the same stop, the amount of time passengers must wait at a transit stop as well as the consistency of a passenger's arrival time at a destination.

Transit signal preemption – The transfer of normal operation of a traffic signal to a special control mode serving a transit vehicle.

Transit signal priority – Adjustments to traffic signal timing to provide more favorable green time to a transit vehicle (bus, streetcar, light rail, and bus rapid transit).

Transitway – See busway/transitway.

Travel demand models – Models that forecast changes in future travel demand on the basis of current conditions and projected socioeconomic characteristics and changes in transportation system design.

Travel mode – 1. A category of roadway characterized by specific right-of-way, technology, and operational features. 2. A particular type of travel (for example, walking, bicycling, bus ride, automobile, or traveling by bus).

Travel speed – See average running speed.

Travel time – The average time spent by vehicles traversing a highway segment, including operational delay.

Travel time rate – The reciprocal of speed, expressed as time per unit distance traveled.

Travel time reliability – 1. The probability that a trip can be completed within a certain threshold time. 2. The variability in travel time for a given trip due to unforeseen causes such as weather, a crash, or an accident.

Traveler information systems – An integrated set of technologies that allow the general public to access real-time or near real-time data on traffic, transit services, incident conditions, travel time, and speed.

Traveler perception model – A model that estimates the average (or range of) response(s) that travelers would give for a given set of conditions (typically subjective or design in nature).

Trucks – A motor vehicle designed primarily for the transport of goods and materials or for the delivery of services other than public transportation.

Turn bay – See auxiliary turn lane.

Turnout – A short segment of a two-lane arterial or collector street, usually widened to the left, that is provided to allow vehicles traveling in the opposite direction to pass a slow-moving vehicle or to have room to safely stop and wait for a gap in traffic to enter.

Two-lane highway – A roadway with two lanes cross-sectionally, one lane for each direction of flow, on which passing maneuvers must be made in the opposing lane.

Two-phase pattern – A type of operation at an isolated intersection where drivers from opposing approaches enter the intersection at roughly the same time.

Two-sided weaving segment – A weaving segment in which all lane-changing weaving maneuvers require at least one lane change to be completed successfully and in which a single lane on each of two roadways followed by a single-lane off-ramp on the opposite side of the freeway.

Two-stage gap acceptance – A condition where a median refuge area is available for vehicles that desire to cross traffic that is separated by a median and that gaps in the near side and far side traffic streams, followed by gaps in the far side traffic stream.

Two-way left-turn lane – A lane in the median area that extends continuously along a street or highway and is marked by pavement markings on both sides and is open to the

AR0074064

through-traffic stream, for vehicles traveling in another direction to make a left turn across all other conflicting traffic streams and driveways.

Two-way stop-controlled – The type of traffic control at an intersection where drivers on the minor street or driveway must wait for a gap in the major street traffic to complete a maneuver.

U

Uncertainty – The range within which a model's estimate of a value is statistically likely to vary from the actual value that

Uncontrolled – Lacking a traffic control device that interrupts traffic flow to give a traffic signal, STOP sign, or YIELD sign.

Understaturated flow – Traffic flow where (a) the arriving flow rate is less than the capacity of a point or segment, (b) no residual queue remains from a prior time period, and (c) traffic flow is unaffected by downstream conditions.

Uniform delay – The first term of the equation for lane group control delay assuming uniform arrival and departure rates during a given duration period.

Uninterrupted flow – Traffic flow on facilities that have no fixed causes of delay or interruption external to the traffic stream; examples include freeways and signalized sections of multilane and two-lane rural highways.

Unit extension – See *passage time*.

Unit width flow rate – The pedestrian flow rate normalized to pedestrians per minute per unit of walkway or crosswalk width.

Unmet demand – The number of vehicles or a specified lane group that cannot be served at any point in time as a result of operational problems (e.g., vehicle queues not cleared by the end of the green phase) or physical problems (e.g., excessive queue spillback from a downstream bottleneck).

Unsignalized intersection – An intersection not controlled by traffic signals.

Upstream – The direction from which traffic is flowing.

Urban – An area typified by high densities of development or concentrations of population, usually by people from several areas with a high degree

Urban street – A street with relatively high density of driveway access, related to an urban land use, and with traffic signals or interruptions by stop or yield signs no farther than 2 mi apart.

Urban street facilities – Extended sections of roadway or arterial streets that include the impacts of traffic signals or other traffic control along the road.

Urban street segment – A length of urban street connecting boundary intersections one end, including the upstream boundary intersection but excluding the downstream boundary intersection.

User perception variability – Variability in user responses that occurs when different drivers experiencing identical conditions are asked to rate the conditions.

Utility – A measure of the value a traveler places on a trip service.

V

Validation – The process by which the analyst checks the ability of a model to predict traffic performance for a stated road system against field measurements of traffic performance that were not used in the calibration process.

Variability – The day-to-day variation in travel demand and congestion within a transportation system.

Vehicle capacity – The maximum number of vehicles that can pass a given point during a specified period under prevailing roadway, traffic, and control conditions.

Vehicle trajectory analysis – The development of performance measures from the perspective of time-space paths of individual vehicles.

Verification – The process by which a software developer and other researchers check the accuracy of a software implementation of traffic-flow rationale theory.

Volume – The total number of vehicles or other roadway users that pass over a given point or roadway segment in both directions or in a given time interval, often 1 h.

Volume-to-capacity (v/c) ratio – The ratio of flow rate to capacity for a system element.

W

Walk interval – A signal display time intended to give pedestrians sufficient time to traverse the width

AR0074065

indication and depart the curb before the pedestrian clearance interval begins.

Walkway – See pedestrian walkway.

Wave speed – The speed at which a shock wave travels upstream or downstream through traffic.

Weaving – The crossing of paths by two traffic streams traveling in the same direction along a significant length of highway, without the aid of traffic control devices (except for guide signs).

Weaving configuration – The organization and continuity of lanes in a weaving segment, which determines lane changing characteristics.

Weaving flow – The traffic movements in a weaving segment that are engaged in weaving movements.

Weaving length – See base length, maximum weaving length, and short length.

Weaving movement – A traffic flow within a weaving segment that requires a lane change to maintain its original path with no more than one lane change. A traffic flow which traverses the segment.

Weaving segment – See freeway weaving segment.

Weaving segment influence area – The base length of the weaving segment plus 500 ft upstream of the entry point to the weaving segment and 500 ft downstream of the exit point from the weaving segment. Entry and exit points are defined as the points where the appropriate edges of the merging and diverging lanes meet.

Weaving width – The total number of lanes between the entry and exit gore areas within a weaving segment, including the auxiliary lane, if present.

Work zone – A segment of highway in which maintenance or construction operations reduce the number of lanes available to traffic, or affect the operational characteristics of traffic flowing through the segment.

Y

Yellow change interval – The period of time that a yellow indication is displayed to alert drivers to the impending presentation of a red indication.

AR0074066

2. LIST OF SYMBOLS

This section lists and defines the symbols and abbreviations used in the HCM, along with their units if applicable. If a symbol has more than one meaning, the chapter or chapters of the specific use are cited in parentheses after the definition.

%HV	percentage of heavy vehicles (decimal)
%OTP	percentage of segment with occupied on-highway parking
%R	percentage of traffic in peak direction
$\%HV_{ap}$	percentage of the total approach flow in the lane with the highest volume (decimal)
A	critical flow ratio for the arterial movements
a_i	passenger-car weighting factor
AADT	annual average daily traffic (veh/day)
A_b	adjusted passings per minute or mode by average bicycle
A_f	percent of free-flow speed (FFS)
A_p	adjusted passings per minute by the average bicycle during the peak 15 min
ATS_d	average travel speed in the analysis direction (mi/h)
ATS_f	average travel speed for the facility (mi/h)
ATS_i	average travel speed for directional segment i (mi/h)
ATS_{fd}	average travel speed in the analysis segment as affected by a passing lane (mi/h)
AWD	average width to nearest obstruction (ft)
b_d	destination adjustment factor
BFFS	base free-flow speed (mi/h)
b_f	platooning factor for lane group
BLOS	bicycle level of service score
b_p	origin adjustment factor
$PPTSF_d$	base percent time-spent-following in the analysis direction
c	base capacity
C	cycle length (s)
$c_{adj,i}$	capacity for lane i (pc/h)
C_m	cycle length (steps)
c_p	adjusted intersection capacity (veh/h)
c_p	average capacity (veh/h)
c_{pce}	available capacity of conversion lane, lane group with protected left-turn operation (veh/h)
c_p'	adjusted capacity in work zone consideration zone
c_{sh}	actual capacity of the shared lane (veh/h)
c_s	capacity of the bicycle lane (bicycle/h)
c_{shared}	capacity of the bypass lane, adjusted for heavy vehicles (pc/h)
c_{stat}	capacity in the analysis direction under prevailing conditions based on ATS (pc/h)
c_{stat}	capacity in the analysis direction under prevailing conditions based on PTSF (pc/h)

AR0074067

C_{LT}	capacity of the left-turn lane, adjusted for heavy vehicles (pc/h)
C_{LTR}	capacity of the left-turn lane, adjusted for heavy vehicles (pc/h)
C_{RT}	capacity of the right-turn lane, adjusted for heavy vehicles (pc/h)
C_{Tf}	common green time with demand-actuated control (s)
CG_{Tf}	common green time between the upstream ramp green and the downstream arterial through green (s)
CG_{Tu}	common green time between the upstream through green and downstream through green (s)
CP	effective critical pause on the conflict path
c_{TR}	capacity of a shared lane (veh/h)
$c_{TR,x}$	capacity of a shared freeway segment with the same flow ratio as the subject lane group segment under equivalent ideal conditions, per lane (pc/h/ln)
$c_{TR,1}$	capacity of all lanes in the shared segment under ideal conditions (pc/h)
c_{TRS}	capacity of the shared segment under equivalent ideal conditions (pc/h/ln)
c_{TT}	capacity of a left-turn movement with permitted left-turn operation (veh/h)
$c_{TT,1}$	capacity of an exclusive left-turn lane group with permitted left-turn operation (veh/h)
$c_{TT,2}$	capacity of an exclusive two-lane left-turn group with permitted left-turn operation (veh/h)
$c_{TT,LT}$	capacity of the through and left-turn movements (veh/h)
$c_{TT,x}$	capacity of movement x
$c_{TT,1}$	capacity of movement 1 (veh/h)
$c_{TT,2}$	movement capacity of the two movements of the subject shared lane (veh/h)
C_{max}	maximum cycle length (s)
c_{max}	merge capacity (veh/h)
C_{min}	minimum cycle length (s)
c_{MT}	non-merge capacity in the inside lane (veh/h)
c_{MT1}	pedestal capacity of conflicting stream 1 (veh/h)
c_{MT2}	lane capacity adjusted for heavy vehicles (pc/h)
CT_i	change period (yellow change interval plus red clearance interval) for phase i (s)
c_{TR}	shared lane capacity for upstream right-turn traffic movement (veh/h)
c_R	capacity of the right-turn movement (veh/h)
$c_{r,1}$	capacity of movement 1 assuming random flow during the unblocked period
c_r	saturation capacity (veh/h)
c_{sr}	critical lane (veh/h)
c_{TT}	capacity of the lane if both storage areas were infinitely long (veh/h)
$c_{TT,1}$	capacity of the shared lane (veh/h)
$c_{TT,2}$	capacity of a shared lane lane group with permitted left-turn operation (veh/h)
c_{TT}	capacity for the exiting through movement (veh/h)
$c_{TT,1}$	capacity for the exiting turn movement (veh/h)
$c_{TT,2}$	critical phase flow rate (veh/h)
d	demand flow rate (veh/h, Chapter 17 control delay (s/veh, Chapter 17), interchange delay (s/veh, Chapter 22)
D	distance (pc/mi/ln, Chapter 17), distance between the two intersections of the interchange (ft, Chapter 22)
d_1	uniform delay (s/veh)

AR0074068

d_1	baseline uniform delay (s/veh)
d_2	incremental delay (s/veh)
d_3	initial queue delay (s/veh)
d_A	control delay on the approach (s/veh)
d_I	arterial street bicycle intersection delay (s)
d_{ped}	average pedestrian delay per pedestrian (pedestrian)
d_R	adjusted volume per destination (veh/h)
d_{RA}	approach control delay for approach (s/veh)
d_{RI}	control delay at the upstream (s/veh)
d_{sl}	lower vehicle acceleration/deceleration delay due to a transit stop (s/veh)
d_T	delay due to turning right turns from the street into cross-street intersection (s/veh)
d_{TH}	through vehicle delay due to left turns (s/veh)
d_{TR}	through vehicle delay due to right turns (s/veh)
$d_{x,y,z}$	control delay for the approach (s/veh)
d_1	bicycle delay, 1-hour rate
D_1	distance to nearest signal-controlled crossing (ft)
D_2	Diversion distance (ft)
D_{adj}	Adjustment for progression adjustment factor
D_c	average density for the lane (pc/mi/ln)
d_p	average pedestrian gap delay (s)
$d_{p,i}$	average gap delay for pedestrians who have initiated delay
d_{ped}	pedestrian hours of delay, as explained in Chapter 21, Generalized Control Delay (pedestrian-hours, Chapter 18)
d_{ped}	vehicle demand on segment (veh), Chapter 21, control delay for lane (s/veh), Chapter 18)
d	intersection control delay (s/veh)
$d_{x,y,z,w,v}$	control delay for the entire intersection (s/veh)
D	distance for deceleration (ft/veh/h)
d	computed control delay for the lane group (s/veh)
$d_{adj,i}$	delay to major left-turning vehicles (s/veh)
D_{adj}	Density in the queue discharge illumination period, excluding approaching flows, lanes (pc/mi/ln)
d_{ped}	merge delay (s/veh)
d_{ped}	pedestrian delay for the inside lane (s/veh)
d_{ped}	delay due to vehicles moving along the route (s/veh)
D_1	phase duration (s)
d_1	average pedestrian delay (s)
$D_{1,1}$	phase duration for phase 1, which occurs just before phase 1 (s)
$D_{1,2}$	phase duration for phase 1, which occurs just after phase 1 (s)
d_{ped}	pedestrian delay when traversing Crosswalk X (s/p)
D_{p1}	phase duration for left-turn phase 1 (s)
$D_{p,ped}$	duration of the phase serving the pedestrian Shared Through movement (s)
$D_{p,1}$	phase duration for coordinated phase 1 (s)

AR0074069

d_1	pedestrian delay when crossing the approach at a signalized intersection (s/p)
d_2	pedestrian diversion delay (s/p)
d_3	pedestrian delay (s/p)
d_4	pedestrian delay when walking parallel to the roadway (s/p)
d_5	transit vehicle delay due to serving passengers (s)
d_6	pedestrian waiting delay (s/p)
d_7	crossing delay (s/p)
d_{Q_1}	distance to the downstream point at the beginning of the upstream unblocked queue (ft)
d_{Q_2}	distance to the downstream queue at the beginning of the upstream queue in approach i (ft)
d_{Q_3}	distance to the downstream queue at the beginning of the upstream ramp queue (ft)
D_r	density in the ramp influence area (pc/mi/ln)
d_r	computed control delay for the right-turn movements (s/veh)
d_t	transit vehicle delay receiving the traffic stream from a transit stop (s/veh)
D_1	speed index for oversaturation
d_1	adjusted uniform delay (s/veh)
$d_{1,ln}$	uniform delay for the movement considered as a separate lane
$d_{1,i}$	uniform delay in shared (left-turn and through lane group (s/veh)
$d_{1,r}$	control delay in shared right-turn and through lane group (s/veh)
DSV	daily service volume
e_i	distance between stored vehicles (= 25 ft)
DSV_i	daily service volume for level of service i (veh/day)
d_i	control delay in exclusive through lane group (s/veh)
d_{i1}	average delay to through vehicles on the inside lane (s/veh)
d_i	total delay in analysis period (veh-h)
d'	through vehicle delay per right-turn vehicle (s/veh)
d_1	delay due to a transit vehicle stop for passenger pickup (s/veh/p)
D_{ij}	cumulative departures (veh)
$D_{ij,t}$	cumulative departures for phase (veh)
d_j	time headway per vehicle (s/veh)
dx_i	length of queue segment i (mi)
e	calibration factor with respect to changes in the travel time rate (Chapter 21), the extension of effective green time rate for clearance interval (s, Chapter 22)
E	weighted events per minute
E_1	equivalent number of through cars for a protected left-turning vehicle
$E_{1,ln}$	unadjusted through car equivalent for a protected left-turning vehicle
E_{11}	equivalent number of through cars for a permitted left-turning vehicle
$E_{11,ln}$	unadjusted through car equivalent for a permitted left-turning vehicle
E_{12}	equivalent number of through cars for a permitted left-turning vehicle when opposed by a queue on a single-lane approach
$E_{12,ln}$	unadjusted through car equivalent for a permitted left-turning vehicle when opposed by a queue on a single-lane approach
e_i	presumed extension of effective green (s)

AR0074070

P_r	passenger car equivalent for recreational vehicles (Chapter 10); equivalent number of through cars for a protected right-turning vehicle (Chapter 18)
P_{RTOR}	equivalent number of through cars for a protected right-turning vehicle at an access point
P_{RT}	modified through-car equivalent for a protected right-turning vehicle
P_T	passenger car equivalent for trucks and buses
P_{TT}	passenger car equivalent for trucks operating at travel speed
p	total events on the path (events/h)
p_1	adjustment factor for area type (HCM, ATDM, LDB chapters)
p_2	adjustment for access points (unit/h)
p_3	proportion of transit vehicle stop acceleration/deceleration delay not due to traffic control
p_b	adjustment factor for blocking effect of local buses that stop within intersection area
p_c	indicator variable for boundary intersections (critical type: 1 [0] = signalized, 0 [1] = two-way stop-controlled)
p_d	median or two-way left-turn lane delay factor
p_f	adjustment for cross section (unit/h)
p_{ped}	pedestrian delay adjustment factor
p_{pk}	proportion of dwell time occurring during effective green
p_r	adjustment for the presence of turn bays, two-way, and two-way left-turn lanes (unit/h)
$PTSF$	free-flow speed (mi/h)
p_g	adjustment factor for approach grade
$p_{g,ATDM}$	grade adjustment factor
$p_{g,PTSF}$	grade adjustment factor for PTSF determination
p_{hv}	two-way left-turn lane factor
p_{hv}	heavy-vehicle adjustment factor
$p_{hv,ATDM}$	heavy-vehicle adjustment factor for average travel speed
$p_{hv,i}$	heavy-vehicle adjustment factor for the ith lane
$p_{hv,PTSF}$	heavy-vehicle adjustment factor for PTSF determination
p_i	signal-phasing adjustment factor
p_j	passenger load factor (passengers/seat)
p_k	adjustment for lateral clearance (unit/h)
p_{lc}	pedestrian-vehicle interaction factor for left-turn groups
p_{ls}	adjustment for lane and shoulder width (unit/h)
p_m	adjustment factor for left-turn vehicle presence in a lane group
p_{np}	adjustment factor for lane utilization
p_{rb}	adjustment for lane width (unit/h)
p_{rt}	adjustment for median type (unit/h)
p_s	number of passing events (events/h)
$p_{s,ATDM}$	adjustment factor for ATDM determination for the percentage of no-passing zones in the analysis direction
$p_{s,PTSF}$	adjustment to PTSF for the percentage of no-passing zones in the analysis segment
PO_4	base cut point for Phase 1 (s)
p^*	driver population factor

AR0074071

L_p	number of passing or refuge lanes
f_p	pedestrian–vehicle adjustment factor
f_{pb}	pedestrian blockage factor for the proportion of time that one lane or an approach is blocked (unitless)
f_{pbx}	entire capacity adjustment factor for pedestrians
$f_{pbx,ped}$	adjustment factor for the effect of pedestrians on the exclusive pedestrian travel speed
$f_{pbx,veh}$	adjustment factor for the effect of a pedestrian on the percent time spent in leaving
f_{pr}	pedestrian–bicycle adjustment factor for right-turn groups
f_{rt}	adjustment for right-turning vehicle presence in the same group
f_s	motorized vehicle speed adjustment factor
f_w	sidewalk width coefficient
f_{wz}	time-in-service scale factor for time period i
f_z	pedestrian travel time factor
f	adjustment factor for traffic pressure
f_{ra}	motorized vehicle–bicycle adjustment factor
f_{rl}	adjustment factor for lane width
f_x	cross-section adjustment factor
g	effective green time (s)
G	green at grade (Chapter 17), green time (s) (Chapter 22)
$G_{ped,i}$	average green interval given that the phase is called by a pedestrian detection (s)
$G_{pv,i}$	average green interval given that the phase is called by a vehicle detection (s)
g'	effective green time adjusted for the presence of downstream queues (s)
G_i	green interval duration for phase i (s)
g_i	available effective green time (s)
g_{ini}	green interval for time-varying initial approach (s)
g_p	effective green time for the bicycle lane (s)
g_{PD}	green interval for the downstream signalized through movement (s)
g_{ps}	supplemental service time for shared-right-lane approaches (s)
g_s	green extension time (s)
g_t	time before the first left-turning vehicle arrives and blocks the shared lane (s)
g_{thru}	maximum time before the first left-turning vehicle arrives and with no vehicle delays are sufficient for through vehicles to depart at saturation flow rate (s)
g_u	effective green time for lane group u (s)
g	effective green time for left-turn phase (s)
G_{max}	maximum green setting (s)
G_{min}	minimum green setting (s)
g_{ns}	effective green time for permitted left-turn operation (s)
G_p	displayed green time associated with g_p (s)
$G_{ped,i}$	minimum green interval duration based on pedestrian crossing time (s)
g_{ped}	pedestrian service time (s)
$g_{ped,rt}$	pedestrian service time for the phase serving the major street through movement (s)
g_{ps}	queue service time during permitted left-turn operation (s)
g_q	upgrading queue service time (g_s for the opposing movement) (s)

AR0074072

G'_i	displayed green interval corresponding to g_i (s)
GR	green interval for the left-turning (or pedestrian) flow (s)
g_s	queue service time (s)
g_u	duration of permitted left-turn green time that is not blocked by an opposing queue (s)
G_{ui}	unblocked green interval duration for a phase (s)
G_{Vi}	green interval for the opposing approach (s)
$h_{d,i,j}$	effective walk time for the phase serving the mixed-use movement (s)
h	average headway for each through lane
$h_{adj,HV}$	average headway of those heavy vehicles in A and N_i (s/veh)
H	maximum headway that the first through vehicle can have and still remain a queue (s/veh)
h_i	headway adjustment (s)
h_i	departure headway or average time between the departures of successive vehicles on a given approach (s)
$h_{adj,i}$	headway adjustment for heavy vehicles (s)
h_i	saturation headway for the subject through approach (s)
h_i	saturation headway or time between departures of successive vehicles on a given approach for a particular case (case i) (s)
$h_{adj,L}$	headway adjustment for left turns (s)
h_{adj}	full stop rate for the segment (stops/veh)
$h_{adj,R}$	headway adjustment for right turns (s)
HR_i	special stop rate for the segment (stops/veh)
i	crossing event index
I	adjustment factor for type, nature (s), and proximity of work activity (see Table Chapter 18 for pedestrian facility adjustment factors (Chapter 18)
$I_{a,i}$	automobile traveler perception score for segment
$I_{a,x}$	bicyclist perception score for intersection
$I_{b,w}$	bicycle perception score for link
$I_{b,i}$	bicyclist perception score for segment
$I_{b,x}$	bicycle perception score for signalized intersection
IO	intersection density, the number of intersections within 5 mi of the center of the subject segment, segment divided by 6 (unitless)
$I_{i,i}$	lane change intensity (C_{ch}/L_i) (veh/ft)
$I_{p,x}$	pedestrian perception score for intersection
$I_{p,w}$	pedestrian perception score for link
$I_{p,i}$	pedestrian perception score for segment
$I_{p,x}$	pedestrian perception score for signalized intersection
I_{pk}	indicator variable for on-street parking occupancy ($= 1$ if $p_{pk} > 20\%$)
I_i	interval between vehicle in queue (s/veh)
I_{sh}	indicator variable for shared lane ($= 1.0$ if the shared left-turn lane is in a shared lane, 0 if the subject left-turn lane is a separate lane)
I_{sp}	indicator variable ($= 1.0$ when equations are used to evaluate delay due to a split phase, 0.0000 when equations are used to evaluate delay due to simple phase)
$I_{t,i}$	transit passenger perception score for segment

AR0074073

i	lane group associated with protected arrival time
k	incremental delay factor
K	proportion of AADT occurring in the peak hour (decimal)
k	density of riders or people (riders/mi)
k_{min}	minimum incremental delay factor
L	cycle lost time (s)
l_1	start-up lost time (s)
$l_{1,p}$	permitted start-up lost time (s)
l_2	clearance lost time (s)
L_a	available queue storage distance (ft/ln)
L_A	length of acceleration lane (ft)
$L_{a,lt}$	available queue storage distance for the combined lane movement (ft/ln)
$L_{a,lt}$	available queue storage distance for the left-turn movement (ft/ln)
$L_{a,th}$	available queue storage distance for the through movement (ft/ln)
$L_{a,rt}$	available queue storage distance for the turn movement (ft/ln)
L_B	base length of the segment, measured from the points at which the edges of the travel lanes of the merging and diverging roadways converge (ft)
LC_{ALL}	total rate of lane changing of all vehicles within the weaving segment (lc/h)
L_c	curb-to-curb crossing distance (ft)
LC_{FR}	minimum number of lane changes that a freeway-to-ramp weaving vehicle must make to complete the freeway-to-ramp movement successfully
LC_L	left-side lateral clearance (ft)
LC_{MIN}	minimum rate of lane changing that must exist for all weaving vehicles to complete their weaving maneuvers successfully (lc/h)
LC_{NW}	total rate of lane changing by nonweaving vehicles within the weaving segment (lc/h)
LC_R	right-side lateral clearance (ft)
LC_{RF}	minimum number of lane changes that a ramp-to-freeway weaving vehicle must make to complete the ramp-to-freeway movement successfully
LC_{RR}	minimum number of lane changes that must be made by one ramp-to-ramp vehicle to complete a weaving maneuver
LC_W	total rate of lane changing by weaving vehicles within the weaving segment (lc/h)
L_d	length of crosswalk (ft)
L_D	length of deceleration lane (ft)
$l_{de,A}$	lost time on the external arterial approach due to the presence of downstream queue (s)
L_{down}	distance between the subject ramp junction and the adjacent downstream ramp junction (ft)
$l_{de,R}$	lost time on the internal ramp approach due to the presence of downstream queue (s)
l_{ds}	additional lost time due to demand starvation (s)
L_{d}	length of the stop-line detection zone (ft)
$L_{d,lt}$	length of the stop-line detection zone in the left-turn lanes (ft)
$L_{d,rt}$	length of the stop-line detection zone in the right-turn lanes (ft)
$L_{d,th}$	length of the stop-line detection zone in the through lanes (ft)
$l_{de,u}$	lost time on the upstream approach due to the presence of a downstream queue (s)
L_{EQ}	equilibrium separation distance

AR0074074

L_v	average vehicle spacing in queue (ft/veh)
L_{vg}	stored heavy-vehicle lane length = 40 (ft)
L_x	length of segment x (mi)
L_p	stored passenger-car lane length = 25 (ft)
L_{pc}	average passenger-car length (ft)
L_1	length of segment traversed by route in Lane 1 (ft)
L_2	distance between adjacent signalized intersections (ft)
L_s	short length of the segment, defined as the distance over which lane changing is not prohibited or discouraged by markings (ft)
L_t	total length of directional segment (mi)
L_u	unsignalized lane (s)
L_v	left-turn flow rate per cycle (veh/cycle)
L_{vv}	distance between the subject ramp junction and the adjacent upstream ramp junction (ft)
L_v	adjusted length of vehicle (ft)
L_{wa}	influence area of the weaving segment (ft)
$L_{x,max}$	maximum length of a queuing segment (ft)
M	pedestrian space (ft²/p)
M_c	meetings per minute of users already on path segment
MAH	maximum allowable headway (s/veh)
MAH^*	equivalent maximum allowable headway for the phase (s/veh)
MAH_c	maximum allowable headway for the concurrent phase that also ends at the barrier (s/veh)
MAH_{lpr}	maximum allowable headway for permitted left-turning vehicles in exclusive lane (s/veh)
$MAH_{l,s}$	maximum allowable headway for protected left-turning vehicles in exclusive lane (s/veh)
$MAH_{l,sh}$	maximum allowable headway for permitted left-turning vehicles in shared lane (s/veh)
MAH_{lsh}	maximum allowable headway for protected left-turning vehicles in shared lane (s/veh)
$MAH_{r,s}$	maximum allowable headway for protected right-turning vehicles in exclusive lane (s/veh)
MAH_{rsh}	maximum allowable headway for permitted right-turning vehicles in shared lane (s/veh)
MAH_{th}	maximum allowable headway for through vehicles (s/veh)
$M_{c,cir}$	corner circulation area per pedestrian (ft²/p)
M_{cw}	crosswalk circulation area per pedestrian (ft²/p)
m_l	set of Lanes available to vehicles that cross Crosswalk l
m_s	average speed of vehicles (mi/h)
m_t	number of lane groups on approach j
N_1	speed index for no-passing (tracing) zone
N_c	total number of expected meetings per minute during the peak 15 min
N_d	modified yield rate (decimal)
n_{15}	count of vehicles during the peak 15-min period (veh)
$n_{15,c}$	count of vehicles traveling on the major street during a 15-min period (veh/h)

AR0074075

v_{ad}	total of vehicles entering the intersection (veh)
N_a	number of traffic signal cross-point approaches along the approach
N_{adj}	number of cross-point approaches on the right side of the opposing direction of travel (points)
N_{adj2}	number of cross-point approaches on the left side of the subject direction of travel (points)
$N_{approach}$	number of lanes in the approach or total through lanes (ln)
N_b	Bus stopping rate in the adjacent approach (buses/h)
N_c	total number of pedestrians in the crossing platoon (p)
N_{cl}	number of lanes in the combined movement (ln)
N_{cr}	number of lanes in the exclusive or shared right-turn lane (ln)
N_{cv}	number of pedestrians arriving at the corner during a cycle having crossed the major street (p)
N_{cw}	number of pedestrians arriving at the corner during a cycle having crossed the major street (p)
N_d	number of exclusive turn lanes in movement group (ln)
N_f	number of fully stopped vehicles (veh/h)
N_{fL}	number of fully stopped vehicles in shared left-turn and through lane group (veh/h)
N_{fR}	number of fully stopped vehicles in shared right-turn and through lane group (veh/h)
N_{fT}	number of fully stopped vehicles in exclusive through lane group (veh/h)
v_g	Arrival count during green (veh)
N_g	number of lane groups (one-way street = 1)
n	number of lanes serving phase movement (ln)
N	number of lanes in approach
N	number of lanes in exclusive left-turn lane group (ln)
N_L	number of lanes in shared left- and right-turn lane group (ln)
N_l	number of lanes in the left turn bay (ln)
N_l	parking maneuver rate adjacent to lane group (maneuvers/h)
n_{lane}	length of the storage area (ft) for the approach lane(s) under consideration (ft/ln)
N_l	number of other lanes in the form veh/h (total lanes, one freeway, 2 for multiple-lane freeway)
N_l	spatial distribution of pedestrians (cf. Chapter 13), number of parallel slopes (Chapter 30)
n_{ln}	number of overlapping pedestrians (p/ft)
N_{ln}	number of pedestrians crossing during an interval (p)
N_m	maximum number of approaching vehicles that could arrive after g_{min} before g_i (veh)
N_m	available queue storage (veh)
$N_{max,m}$	available queue storage for the conflicting movement (veh)
$N_{max,L}$	maximum queue storage for the left turn movement (veh)
$N_{max,T}$	maximum queue storage for the through movement (veh)
$N_{max,R}$	maximum queue storage for the right turn movement (veh)
N_o	number of lanes in exclusive/shared left-turn lane group (ln)
$N_{o,adj}$	number of lanes for the upstream ramp left-turning movement
N_{pR}	number of right-turn channelized pedestrian signals (see Chapter 18)
n_r	number of vehicles per cycle (= 2.0 veh/ln)

AR0074076

N_{th}	number of lanes in shared lane or exclusive through lane group (thr)
N_{tr}	number of lanes in shared right-turn and through lane group (thr)
N_v	total number of vans
N_{vh}	number of through lanes (shared or exclusive) (lan)
N_{vh}	number of through lanes (shared or exclusive) (lan)
N_{vo}	total number of circulating pedestrians arriving on the walkway (ped)
N_w	number of lanes in a subject segment
N_{wo}	average number of lanes along the subject crosswalk (ln/pl)
N_{wo}	number of lanes in the intersection (ln)
N_x	number of weaving vehicles that cross the walk and pedestrian flow interval (ped)
N_{wb}	number of lanes from which a weaving maneuver may be completed with one lane change in the same direction
n_x	number of cells necessary to exhaust the green in one cycle
O_c	adjusted volume for origin (veh/h)
OCC_{bi}	bicycle occupancy
Occ_{ped}	pedestrian occupancy after the opposing queue clears
OCC_r	relevant conflicting vehicle occupancy
O_v	volume for origin (veh/h)
P	proportion of vehicles arriving during the green interval
P^*	adjustment to the major-street left-turn or major-street through impedance factor
P_{adj}	proportion of N_{wo} that can be assumed to be a left turn from the subject direction of travel
P_b	proportion of time blocked (decimal)
P_{bl}	proportion of time that the subject movement is blocked by the major-street platoon
$P_{bx,i}$	probability that an individual will respond with a score of B, C, D, E, or F
P_{cb}	proportion of slows on adjacent walk benches (decimal)
P_{cb}	probability of two blocked lanes in the opposing direction
P_{cb}	probability of two blocked lanes in the subject direction
$P_{curb,o}$	proportion of sidewalk length adjacent to a building or curb (decimal)
P	pavement condition rating
PC	pedestrian platooning ratio
$P_{d,i,x}$	probability that an individual will respond with a score of C, D, E, or F
$P_{d,o}$	proportion of segment with curb on the right-hand side (decimal)
$P_{dx,i}$	probability that an individual will respond with a score of D, E, or F
P_{fo}	probability of delayed passing in opposing direction
P_{fs}	probability of delayed passing in subject direction
P_{ix}	probability that an individual will respond with a score of E or F
P_{ix}	probability that an individual will respond with a score of F
P_{LD}	proportion of diverging traffic remaining in Lanes 1 and 2 immediately upstream of the deceleration lane
P_{LS}	proportion of sidewalk length adjacent to a fence or low wall (decimal)
P_{LT}	proportion of freeway vehicles remaining in Lanes 1 and 2 immediately upstream of the on-ramp deceleration area
PHF	peak hour factor

AR0074077

P_{HV}	percentage of heavy vehicles in the corresponding movement group (%)
$P_{HV,o}$	adjusted percentage of heavy vehicles in the opposing shared lane demand flow rate (%)
p	probability for user group
p_i	seed proportion of volume from origin to destination i (decimal)
p_j	turning proportion for movement group (%)
P_L	proportion of left-turning vehicles in the shared lane
P_{LT}	probability of a vehicle moving from a left-turn lane to a through lane
P_o	proportion of left-turning vehicles in the subject approach (decimal)
P_{OL}	proportion of left-turning vehicles in the lane
$P_{OL,i-j}$	proportion of intersections with left-turn lanes (e.g., bay) on segment (decimal)
P_{OL}	proportion of left-turning vehicles in the opposing traffic stream
P_{pd}	probability of delayed passing for mode m
P_{pm}	probability of blocked lane in opposing direction
P_{pm}	probability of blocked lane in subject direction
P_R	proportion of heavy vehicles turning on red (decimal)
P_{RT}	probability of left-turn bay overflow (decimal)
P_{sp}	proportion of on-street parking occupied (decimal)
P_T	proportion of recreational vehicles in the traffic stream (Chapter 11), proportion of right-turning vehicles in the shared lane (Chapter 31)
P_{TR}	proportion of link length with restrictive median (decimal)
P_U	proportion of right-turning vehicles on the subject approach (decimal)
P_{UL}	proportion of right-turning vehicles in the lane
P_{UT}	proportion of drop-down gap cut with Cutler's (decimal)
P_v	proportion of buses and trucks in the traffic stream
PT	passage time setting (s)
P_{TH}	proportion of trucks operating at slow speed (decimal)
P_{TM}	total probability of delayed passing
PT_L	passage time setting for phase serving left-turning vehicles (s)
PT_R	passage time setting for phase serving right-turning vehicles (s)
$PTSF_a$	percent time-spent-following in the analysis direction (decimal)
$PTSF_b$	percent time-spent-following in the opposing direction (decimal)
$PTSF_{LT}$	percent time-spent-following for segment i (decimal)
$PTSF_p$	percent time-spent-following for segment as affected by the presence of a passing lane (decimal)
PT_T	passage time setting for phase serving through vehicles (s)
P_{UL}	proportion of turning vehicles in the shared lane L_1 or P_R (decimal)
$P_{walk,adj}$	proportion of sidewalk length adjacent to a window display (by decimal)
p_x	probability of phase termination by extension to the maximum green limit
q	demand flow rate = v/PHF (veh/h)
Q	back-of-queue size (veh/ln)
q^*	actual flow rate for the phase (veh/h)
q_{adj}	adjusted flow rate in time-space of upstream intersection (veh/h/ln) or v_o (veh/h/ln)
$q_{adj,i}$	departure flow rate in time-space of upstream intersection i (veh/h/ln)

AR0074078

Q_1	first-term back-of-queue size (veh/ln)
Q_2	second-term back-of-queue size (veh/ln)
$Q_{2,T}$	second-term back-of-queue size for shared left-turn and through lane group (veh/ln)
$Q_{2,R}$	second-term back-of-queue size for shared right-turn and through lane group (veh/ln)
$Q_{2,T}$	second-term back-of-queue size for exclusive through lane group (veh/ln)
Q_3	back-of-queue size (veh/ln)
Q_3	third-term back-of-queue size (veh/ln)
$Q_{3,T}$	third-term back-of-queue size for shared left-turn and through lane group (veh/ln)
$Q_{3,R}$	third-term back-of-queue size for shared right-turn and through lane group (veh/ln)
Q_3	third-term back-of-queue size for exclusive through lane group (veh/ln)
Q_{95}	95th percentile queue (veh)
Q_a	estimated average per lane queue length for the through movement in the downstream (protected) link at the beginning of upstream critical Phase A (ft)
Q_b	initial queue at the start of the analysis period (veh)
$Q_{b,ini}$	initial queue for the unblocked movement (veh)
Q_c	arrival flow rate at downstream lane group (veh/s)
Q_e	queue at the end of the analysis period (veh)
Q_{e1}	queue at the end of the analysis period when $v = c_m$ and $Q_{e1} > 0$ (veh)
Q_e	queue size at the end of t_g (veh)
Q_g	arrival flow per during the effective green time (veh/s)
Q_i	lane adjusted saturation flow rate for lane group (passenger cars/h)
Q_i	queue size at the end of interval i (veh)
$Q_{max,n}$	length of the queue stored at the internal approach at the beginning of the last red during which the approach has a remaining observation interval
Q_o	outside lane flow rate = $v_o/3600$ (veh/s)
Q_p	bicycle demand in the opposing direction (bicycles/h)
Q_p	queue size at the end of permitted service time (veh)
Q_{pr}	queue size at the end of permitted service time t_{pr} adjusted for saturation (veh)
Q_r	queue size at the start of t_g (veh)
q_r	arrival flow rate during the effective red time (veh/s)
Q_r	queue size at the end of effective red time (t_r) (veh)
Q_s	estimated average per lane queue length for the through movement in the downstream (protected) link at the beginning of upstream critical Phase B (ft)
Q_{sh}	bicycle demand in the same direction (bicycles/h)
Q_{sq}	average queue length for the movement considered at the end of the cycle (veh)
Q_t	total hourly entering pedestrian volume (peds/h)
Q_{tw}	total time spent by pedestrians waiting to cross the major street during one cycle (p-s)
r	effective red time ($= C - g$) (s)
R	manual adjustment for on-ramps (veh/h, Chapter 10); radius of corner curb (Chapter 16); critical flow ratio for the exit ramp movement (Chapter 22)
R_1, R_2	intermediate calculation variables
r_a	deceleration rate = 3.5 (ft/s²)
r_d	transit vehicle deceleration rate (ft/s²)
R_r	red clearance interval (s)

AR0074079

R_{pc}	pedestrian-vehicle conflict rate (ped/h)
s_a	adjusted saturation flow rate (pc/h/ln)
s_b	base saturation flow rate (pc/h/ln)
s_{bc}	base saturation flow rate for conflicting lane (pc/h/ln)
s_{bx}	base saturation flow rate for exclusive turn lane (pc/h/ln)
s_{bx1}	base saturation flow rate for exclusive left-turn lane (pc/h/ln)
s_{bx2}	base saturation flow rate for exclusive right-turn lane (pc/h/ln)
s_{bx12}	base saturation flow rate for exclusive left-turn lane with protected operation (pc/h/ln)
s_{bx3}	base saturation flow rate for exclusive left-turn lane with permitted operation (pc/h/ln)
s_{bx4}	base saturation flow rate for exclusive left-turn lane group with permitted operation (pc/h/ln)
s_c	saturation flow rate for conflicting lane (pc/h/ln)
s_d	saturation flow rate for downstream segment (pc/h/ln)
s_{dx}	saturation flow rate for exclusive turn lane (pc/h/ln)
s_{dx1}	saturation flow rate for exclusive left-turn lane (pc/h/ln)
s_{dx2}	saturation flow rate for exclusive right-turn lane (pc/h/ln)
s_{dx12}	saturation flow rate for exclusive left-turn lane with protected operation (pc/h/ln)
s_{dx3}	saturation flow rate for exclusive left-turn lane with permitted operation (pc/h/ln)
s_{dx4}	saturation flow rate for exclusive left-turn lane group with permitted operation (pc/h/ln)
s_f	saturation flow rate for subject approach (pc/h/ln)
s_{fx}	saturation flow rate for exclusive turn lane (pc/h/ln)
s_{fx1}	saturation flow rate for exclusive left-turn lane (pc/h/ln)
s_{fx2}	saturation flow rate for exclusive right-turn lane (pc/h/ln)
s_{fx12}	saturation flow rate for exclusive left-turn lane with protected operation (pc/h/ln)
s_{fx3}	saturation flow rate for exclusive left-turn lane with permitted operation (pc/h/ln)
s_{fx4}	saturation flow rate for exclusive left-turn lane group with permitted operation (pc/h/ln)
s_g	saturation flow rate for shared left- and right-turn lane group (pc/h/ln)
s_{gx}	saturation flow rate for exclusive left-turn lane with protected operation (pc/h/ln)
s_{gx1}	saturation flow rate for exclusive left-turn lane with protected operation (pc/h/ln)
s_{gx2}	saturation flow rate for exclusive right-turn lane with protected operation (pc/h/ln)
s_{gx12}	saturation flow rate for exclusive left-turn lane with protected operation (pc/h/ln)
s_{gx3}	saturation flow rate for exclusive left-turn lane with permitted operation (pc/h/ln)
s_{gx4}	saturation flow rate for exclusive left-turn lane group with permitted operation (pc/h/ln)
s_h	saturation flow rate for shared left- and right-turn lane group (pc/h/ln)
s_{hx}	saturation flow rate for exclusive left-turn lane with protected operation (pc/h/ln)
s_{hx1}	saturation flow rate for exclusive left-turn lane with protected operation (pc/h/ln)
s_{hx2}	saturation flow rate for exclusive right-turn lane with protected operation (pc/h/ln)
s_{hx12}	saturation flow rate for exclusive left-turn lane with protected operation (pc/h/ln)
s_{hx3}	saturation flow rate for exclusive left-turn lane with permitted operation (pc/h/ln)
s_{hx4}	saturation flow rate for exclusive left-turn lane group with permitted operation (pc/h/ln)
s_i	saturation flow rate for shared left- and right-turn lane group (pc/h/ln)
s_{ix}	saturation flow rate for exclusive left-turn lane with protected operation (pc/h/ln)
s_{ix1}	saturation flow rate for exclusive left-turn lane with protected operation (pc/h/ln)
s_{ix2}	saturation flow rate for exclusive right-turn lane with protected operation (pc/h/ln)
s_{ix12}	saturation flow rate for exclusive left-turn lane with protected operation (pc/h/ln)
s_{ix3}	saturation flow rate for exclusive left-turn lane with permitted operation (pc/h/ln)
s_{ix4}	saturation flow rate for exclusive left-turn lane group with permitted operation (pc/h/ln)
s_j	saturation flow rate for shared left- and right-turn lane group (pc/h/ln)
s_{jx}	saturation flow rate for exclusive left-turn lane with protected operation (pc/h/ln)
s_{jx1}	saturation flow rate for exclusive left-turn lane with protected operation (pc/h/ln)
s_{jx2}	saturation flow rate for exclusive right-turn lane with protected operation (pc/h/ln)
s_{jx12}	saturation flow rate for exclusive left-turn lane with protected operation (pc/h/ln)
s_{jx3}	saturation flow rate for exclusive left-turn lane with permitted operation (pc/h/ln)
s_{jx4}	saturation flow rate for exclusive left-turn lane group with permitted operation (pc/h/ln)
s_k	saturation flow rate for shared left- and right-turn lane group (pc/h/ln)
s_{kx}	saturation flow rate for exclusive left-turn lane with protected operation (pc/h/ln)
s_{kx1}	saturation flow rate for exclusive left-turn lane with protected operation (pc/h/ln)
s_{kx2}	saturation flow rate for exclusive right-turn lane with protected operation (pc/h/ln)
s_{kx12}	saturation flow rate for exclusive left-turn lane with protected operation (pc/h/ln)
s_{kx3}	saturation flow rate for exclusive left-turn lane with permitted operation (pc/h/ln)
s_{kx4}	saturation flow rate for exclusive left-turn lane group with permitted operation (pc/h/ln)
s_l	saturation flow rate for shared left- and right-turn lane group (pc/h/ln)
s_{lx}	saturation flow rate for exclusive left-turn lane with protected operation (pc/h/ln)
s_{lx1}	saturation flow rate for exclusive left-turn lane with protected operation (pc/h/ln)
s_{lx2}	saturation flow rate for exclusive right-turn lane with protected operation (pc/h/ln)
s_{lx12}	saturation flow rate for exclusive left-turn lane with protected operation (pc/h/ln)
s_{lx3}	saturation flow rate for exclusive left-turn lane with permitted operation (pc/h/ln)
s_{lx4}	saturation flow rate for exclusive left-turn lane group with permitted operation (pc/h/ln)
s_m	saturation flow rate for shared left- and right-turn lane group (pc/h/ln)
s_{mx}	saturation flow rate for exclusive left-turn lane with protected operation (pc/h/ln)
s_{mx1}	saturation flow rate for exclusive left-turn lane with protected operation (pc/h/ln)
s_{mx2}	saturation flow rate for exclusive right-turn lane with protected operation (pc/h/ln)
s_{mx12}	saturation flow rate for exclusive left-turn lane with protected operation (pc/h/ln)
s_{mx3}	saturation flow rate for exclusive left-turn lane with permitted operation (pc/h/ln)
s_{mx4}	saturation flow rate for exclusive left-turn lane group with permitted operation (pc/h/ln)
s_n	saturation flow rate for shared left- and right-turn lane group (pc/h/ln)
s_{nx}	saturation flow rate for exclusive left-turn lane with protected operation (pc/h/ln)
s_{nx1}	saturation flow rate for exclusive left-turn lane with protected operation (pc/h/ln)
s_{nx2}	saturation flow rate for exclusive right-turn lane with protected operation (pc/h/ln)
s_{nx12}	saturation flow rate for exclusive left-turn lane with protected operation (pc/h/ln)
s_{nx3}	saturation flow rate for exclusive left-turn lane with permitted operation (pc/h/ln)
s_{nx4}	saturation flow rate for exclusive left-turn lane group with permitted operation (pc/h/ln)
s_o	saturation flow rate for shared left- and right-turn lane group (pc/h/ln)

s_{ox1}	saturation flow rate for exclusive left-turn lane with protected operation (pc/h/ln)
s_{ox2}	saturation flow rate for exclusive right-turn lane with protected operation (pc/h/ln)
s_{ox12}	saturation flow rate for exclusive left-turn lane with protected operation (pc/h/ln)
s_{ox3}	saturation flow rate for exclusive left-turn lane with permitted operation (pc/h/ln)
s_{ox4}	saturation flow rate for exclusive left-turn lane group with permitted operation (pc/h/ln)
s_p	saturation flow rate for shared left- and right-turn lane group (pc/h/ln)
s_{px}	saturation flow rate for exclusive left-turn lane with protected operation (pc/h/ln)
s_{px1}	saturation flow rate for exclusive left-turn lane with protected operation (pc/h/ln)
s_{px2}	saturation flow rate for exclusive right-turn lane with protected operation (pc/h/ln)
s_{px12}	saturation flow rate for exclusive left-turn lane with protected operation (pc/h/ln)
s_{px3}	saturation flow rate for exclusive left-turn lane with permitted operation (pc/h/ln)
s_{px4}	saturation flow rate for exclusive left-turn lane group with permitted operation (pc/h/ln)
s_q	saturation flow rate for shared left- and right-turn lane group (pc/h/ln)
s_{qx}	saturation flow rate for exclusive left-turn lane with protected operation (pc/h/ln)
s_{qx1}	saturation flow rate for exclusive left-turn lane with protected operation (pc/h/ln)
s_{qx2}	saturation flow rate for exclusive right-turn lane with protected operation (pc/h/ln)
s_{qx12}	saturation flow rate for exclusive left-turn lane with protected operation (pc/h/ln)
s_{qx3}	saturation flow rate for exclusive left-turn lane with permitted operation (pc/h/ln)
s_{qx4}	saturation flow rate for exclusive left-turn lane group with permitted operation (pc/h/ln)
s_r	saturation flow rate for shared left- and right-turn lane group (pc/h/ln)
s_{rx}	saturation flow rate for exclusive left-turn lane with protected operation (pc/h/ln)
s_{rx1}	saturation flow rate for exclusive left-turn lane with protected operation (pc/h/ln)
s_{rx2}	saturation flow rate for exclusive right-turn lane with protected operation (pc/h/ln)
s_{rx12}	saturation flow rate for exclusive left-turn lane with protected operation (pc/h/ln)
s_{rx3}	saturation flow rate for exclusive left-turn lane with permitted operation (pc/h/ln)
s_{rx4}	saturation flow rate for exclusive left-turn lane group with permitted operation (pc/h/ln)
s_s	saturation flow rate for shared left- and right-turn lane group (pc/h/ln)
s_{sx}	saturation flow rate for exclusive left-turn lane with protected operation (pc/h/ln)
s_{sx1}	saturation flow rate for exclusive left-turn lane with protected operation (pc/h/ln)
s_{sx2}	saturation flow rate for exclusive right-turn lane with protected operation (pc/h/ln)
s_{sx12}	saturation flow rate for exclusive left-turn lane with protected operation (pc/h/ln)
s_{sx3}	saturation flow rate for exclusive left-turn lane with permitted operation (pc/h/ln)
s_{sx4}	saturation flow rate for exclusive left-turn lane group with permitted operation (pc/h/ln)
s_t	saturation flow rate for shared left- and right-turn lane group (pc/h/ln)
s_{tx}	saturation flow rate for exclusive left-turn lane with protected operation (pc/h/ln)
s_{tx1}	saturation flow rate for exclusive left-turn lane with protected operation (pc/h/ln)
s_{tx2}	saturation flow rate for exclusive right-turn lane with protected operation (pc/h/ln)
s_{tx12}	saturation flow rate for exclusive left-turn lane with protected operation (pc/h/ln)
s_{tx3}	saturation flow rate for exclusive left-turn lane with permitted operation (pc/h/ln)
s_{tx4}	saturation flow rate for exclusive left-turn lane group with permitted operation (pc/h/ln)
s_u	saturation flow rate for shared left- and right-turn lane group (pc/h/ln)
s_{ux}	saturation flow rate for exclusive left-turn lane with protected operation (pc/h/ln)
s_{ux1}	saturation flow rate for exclusive left-turn lane with protected operation (pc/h/ln)
s_{ux2}	saturation flow rate for exclusive right-turn lane with protected operation (pc/h/ln)
s_{ux12}	saturation flow rate for exclusive left-turn lane with protected operation (pc/h/ln)
s_{ux3}	saturation flow rate for exclusive left-turn lane with permitted operation (pc/h/ln)
s_{ux4}	saturation flow rate for exclusive left-turn lane group with permitted operation (pc/h/ln)
s_v	saturation flow rate for shared left- and right-turn lane group (pc/h/ln)
s_{vx}	saturation flow rate for exclusive left-turn lane with protected operation (pc/h/ln)
s_{vx1}	saturation flow rate for exclusive left-turn lane with protected operation (pc/h/ln)
s_{vx2}	saturation flow rate for exclusive right-turn lane with protected operation (pc/h/ln)
s_{vx12}	saturation flow rate for exclusive left-turn lane with protected operation (pc/h/ln)
s_{vx3}	saturation flow rate for exclusive left-turn lane with permitted operation (pc/h/ln)
s_{vx4}	saturation flow rate for exclusive left-turn lane group with permitted operation (pc/h/ln)
s_w	saturation flow rate for shared left- and right-turn lane group (pc/h/ln)
s_{wx}	saturation flow rate for exclusive left-turn lane with protected operation (pc/h/ln)
s_{wx1}	saturation flow rate for exclusive left-turn lane with protected operation (pc/h/ln)
s_{wx2}	saturation flow rate for exclusive right-turn lane with protected operation (pc/h/ln)
s_{wx12}	saturation flow rate for exclusive left-turn lane with protected operation (pc/h/ln)
s_{wx3}	saturation flow rate for exclusive left-turn lane with permitted operation (pc/h/ln)
s_{wx4}	saturation flow rate for exclusive left-turn lane group with permitted operation (pc/h/ln)
s_x	saturation flow rate for shared left- and right-turn lane group (pc/h/ln)
s_{xx}	saturation flow rate for exclusive left-turn lane with protected operation (pc/h/ln)
s_{xx1}	saturation flow rate for exclusive left-turn lane with protected operation (pc/h/ln)
s_{xx2}	saturation flow rate for exclusive right-turn lane with protected operation (pc/h/ln)
s_{xx12}	saturation flow rate for exclusive left-turn lane with protected operation (pc/h/ln)
s_{xx3}	saturation flow rate for exclusive left-turn lane with permitted operation (pc/h/ln)
s_{xx4}	saturation flow rate for exclusive left-turn lane group with permitted operation (pc/h/ln)
s_y	saturation flow rate for shared left- and right-turn lane group (pc/h/ln)
s_{yx}	saturation flow rate for exclusive left-turn lane with protected operation (pc/h/ln)
s_{yx1}	saturation flow rate for exclusive left-turn lane with protected operation (pc/h/ln)
s_{yx2}	saturation flow rate for exclusive right-turn lane with protected operation (pc/h/ln)
s_{yx12}	saturation flow rate for exclusive left-turn lane with protected operation (pc/h/ln)
s_{yx3}	saturation flow rate for exclusive left-turn lane with permitted operation (pc/h/ln)
s_{yx4}	saturation flow rate for exclusive left-turn lane group with permitted operation (pc/h/ln)
s_z	saturation flow rate for shared left- and right-turn lane group (pc/h/ln)
s_{zx}	saturation flow rate for exclusive left-turn lane with protected operation (pc/h/ln)
s_{zx1}	saturation flow rate for exclusive left-turn lane with protected operation (pc/h/ln)
s_{zx2}	saturation flow rate for exclusive right-turn lane with protected operation (pc/h/ln)
s_{zx12}	saturation flow rate for exclusive left-turn lane with protected operation (pc/h/ln)
s_{zx3}	saturation flow rate for exclusive left-turn lane with permitted operation (pc/h/ln)
s_{zx4}	saturation flow rate for exclusive left-turn lane group with permitted operation (pc/h/ln)

AR0074080

$S_{p,i}$	pedestrian speed (mi/h)
S_{pb}	free-flow pedestrian walking speed (ft/s)
S_{pk}	peak speed (mi/h)
$s_{prot,pce}$	prevailing saturation flow rate for lane group (pc/h)
$s_{sh,i}$	shared lane discharge flow rate for upstream right-turn traffic movement (veh/h)
s_t	saturation flow rate for exclusive right-turn lane group with permitted operation (veh/h/ln)
v_p	average speed in the pedestrian circulation area (mi/h)
S_{pc}	adjusted free-flow bicycle running speed (mi/h)
N_{tr}	transit vehicle running speed (mi/h)
N_t	threshold speed for running or stopped vehicles (= 5.0 mi/h)
s_{tr}	saturation flow rate for shared left-turn and through lane group with permitted operation (veh/h/ln)
$s_{tr,pce}$	maximum saturation flow rate for shared left-turn and through lane group with permitted operation (pc/h/ln)
$s_{tr,1}$	saturation flow rate for shared left-turn and through lane group during Period 2 (veh/h/ln)
$S_{tr,v}$	average transit speed (mi/h)
s_{tr}	saturation flow rate for shared left-turn or right-turn and through lane group with permitted operation (veh/h/ln)
s_u	saturation flow rate for exclusive through lane group (veh/h/ln)
S_v	vehicle speed factor
$S_{v,th}$	travel speed of through vehicles for the segment (mi/h)
$S_{v,th,b}$	travel speed of through bicycles along the segment (mi/h)
s_v	saturation flow rate for an exclusive through lane (= base saturation flow rate adjusted for lane width, heavy vehicles, grade, parking, buses, and area type) (veh/h/ln)
$S_{v,th,p}$	travel speed of through pedestrians for the segment (ft/s)
$S_{v,tr,v}$	travel speed of transit vehicles on the segment (mi/h)
SV_i	service volume for LOS i (veh/h)
S_w	average speed of weaving vehicles within the weaving segment (mi/h)
s_{wt}	transit wait ride score
t	duration of unmet demand in the analysis period (= Chapter 16, path segment travel time for average analysis hour, Chapter 22)
T	analysis time period
t'	platoon arrival time (steps)
t_1	blocked period duration (steps)
t_2	segment running time (steps)
T_a	time at which a vehicle would have arrived at the stop line if it had been driving up at the reference speed
T_d	time at which a vehicle would have arrived at the stop line if it had been driving up at the running speed
T_e	time at which a vehicle is discharged at the stop line
t_{eq}	adjustment factor for intersection geometry
v_t	average duration of unmet demand in the analysis period (h)
v_u	adjusted duration of unmet demand in the analysis period (h)
v_{ur}	unmet demand rate (pc/h)

AR0074081

T_{cp} base travel time rate = 60 for the central business district of a metropolitan area with 5 million persons or more; 25 increased 10 (min/mi)

t_d time until splitback (s)

t_g queue clearing time (Chapter 15, critical headway for a single protection; Chapter 14)

t_{go} base critical headway (s)

t_{hv} adjustment factor for grade (s)

t_{HV} adjustment factor for heavy vehicles (s)

t_c critical headway (i.e., the minimum time that allows intersection entry for one minor stream vehicle) for movement x (s)

t_f critical gap (s)

t_{fo} base follow-up time of the right-turn vehicle (s)

t_l overall time (s)

t_L duration of time interval during which the arrival flow rate and capacity flow rate are constant (h)

t_p average waiting time due to lateral gaps (s)

t_{pr} average waiting time due to lateral gaps (min/veh)

t_s follow-up headway (s, Chapter 21; service time for fully stopped vehicles (s, Chapter 30)

t_{sw} base follow-up headway (s)

t_{sw} adjustment factor for heavy vehicles (1.0 for major streets with one lane in each direction; 2.0 for major streets with two or three lanes in each direction)

t_t follow-up headway (i.e., the time between the departure of one vehicle from the intersection and the departure of the next vehicle under a continuous queue condition) for minor movement x (s)

t_{tv} follow-up headway (s)

t lost time for ith vehicle in queue (s, Chapter 4); duration of unmet demand for time period (h, Chapter 18)

t transit vehicle running time loss (sec/veh)

t_v lost time per phase (s)

t_x adjusted lost time (i.e., the time during which the separated intersections are not used effectively by any movement) (s)

t_x' adjusted lost time for the internal approaches (s)

t_{thr} threshold lane time = 30 (typical) (min)

t_v critical design headway = 3.2 (s)

t_{vt} total lateral clearance (ft)

T_{wk} crosswalk occupancy time (s)

U_p analysis time period

v_a pedestrian perception of signal indication and curb departure time (= 2.0 s)

v_p pedestrian walking speed (s)

v_{pa} passenger-car hourly lane rate (pcphpl)

v_r lane distribution of x (pcu)

v_s saturation flow rate (pcphpl)

v_{sh} segment hourly flow rate = [average] (veh/h)

V_{tp} total ramp demand (pcph/pln)

v_x segment hourly flow rate for x movement (veh)

AR0074082

t_s	pedestrian start-up time and end clearance time (s; Chapter 19); service time or occupancy time spent by a vehicle in first position waiting to depart (s; Chapter 30)
TS_p	time-space available for travel by pedestrian (ped-s)
$TS_{p,ave}$	average crosswalk time-space (ped-s)
TS_p	available crosswalk time-space (ped-s)
TS_p'	effective available crosswalk time-space (ped-s)
ts_{tv}	time-space occupied by turning vehicles (ped-s)
t_t	duration of trapezoid or triangle in interval (s)
TT	total travel time of all vehicles in segment (veh-h)
TT_{av}	total travel time experienced by all vehicles traversing the subject segment during the 15-min analysis period (veh-h)
v	speed of average bicycle (mi/h)
v_c	constrained speed of the first through vehicle given that it is delayed (ft/s)
v_r	right-turn speed (ft/s)
v	service flow rate
V	demand volume under prevailing conditions (veh/h)
v	flow rate for the outside lane (veh/h/ln)
v_{12}	demand flow rate in Lanes 1 and 2 of the freeway immediately upstream of the ramp influence area (pc/h)
v_{15}	pedestrian flow rate during the peak 15 min (p/h)
V_{15}	volume during the peak 15 min of the analysis hour (veh/15 min)
v_a	flow rate in the adjacent through lane (veh/h/ln)
v_{av}	flow rate in Lane 3 of the freeway (pc/h/ln)
v_{ad}	adjusted arrival volume in the shared lane (veh/h)
v_{ca}	flow rate of pedestrians traveling through the corner from Sidewalk A to Sidewalk B, or vice versa (p/h)
v_{ch}	volume of flow rate for approach (veh/h)
v_c/N_c	arterial flow feeding the subject queue, divided by the respective number of lanes
$v_{c,T}$	average demand flow rate per through lane (upstream of any turn bays on the approach) (vehicle/lane)
$v_{c,up,T}$	upstream arterial through flow (v/h)
v_{cy}	bicycle flow rate (bicycles/h)
$v_{cy,g}$	bicycle flow rate during the green indication (bicycles/h)
v_d	conflicting flow rate
$v_{d,sh}$	shadow conflicting flow rate (veh/h), assumed to be 1,000N, where N is the number of through lanes per direction on the major street
$v_{d,x}$	conflicting flow rate (pc/h)
$v_{d,x}$	conflicting flow for movement x during the unblocked period (veh/h)
$v_{d,x}$	conflicting flow rate for movement x (veh/h)
v_{ped}	flow rate of pedestrians arriving at the corner to cross the minor street (p/h)
v_p	flow rate of pedestrians arriving at the corner to cross the minor street (p/h)
v_{pa}	flow rate on the adjacent downstream ramp (pc/h)
v_{pce}	demand flow rate for ATSIs for conflicting analysis lane (pc/h)
$v_{pce,av}$	demand flow rate in the analysis direction for estimation of FFS (pc/h)

AR0074083

v_p	flow rate of pedestrians arriving at the corner to cross the major street (p/h)
v_{pb}	flow rate of pedestrians arriving at the corner to cross the major street (p/h)
$P_{v,15min}$	adjusted 15-min visit demand flow rate per parking configuration (veh/h)
v_p	entry flow rate
v_x	exit flow rate
$v_{x,y}$	conflicting opposing flow rate (pc/h)
$v_{x,y}$	flow rate on freeway immediately upstream of the ramp influence area under study (pc/h)
v_{FW}	freeway to freeway demand flow rate in the weaving segment (pc/h)
v_{FW}	flow rate on the freeway immediately downstream of the merge or diverge area (pc/h)
v_{FO}	freeway to ramp demand flow rate in the weaving segment (pc/h)
v_g	demand flow rate for movement group (veh/h)
v_{g1}	demand flow rate in the exclusive lane with the highest flow rate of all exclusive lanes in movement group (veh/h)
v_p	pedestrian demand during the analysis hour (p/h)
v_p	demand flow rate for movement i (pc/h, Chapter 19); planned volume for phase i (veh/h, Chapter 28)
v_i	demand volume for movement i (veh/h, Chapter 19); special pedestrian analysis (pc/h, Chapter 23)
v_i'	demand flow rate (veh/cycle/in)
v_{ll}	major street through vehicles in shared lane (veh/h)
v_{lr}	major street turning vehicles in shared lane (veh/h)
v_{LOS}	demand flow rate for LOS evaluation (pc/h)
v_{ij}	volume starting from origin i and exiting at destination j (veh/h)
$v_{ij,t}$	demand flow rate for movement i (pc/h)
v_{LOS}	demand flow rate for determination of PTSF (pc/h)
v_m	flow rate for movement m
v_{ll}	demand flow rate in exclusive left-turn lane (veh/h)
v_{lr}	major street through plus right-turn volume (veh/h)
v_{LT}	through and left-turn volume (veh/h)
v_{lr}	shared through and right-turn lane group (veh/h)
v_{lr}	shared left-turn demand flow rate (veh/h)
$v_{lr,sh}$	permitted left-turn demand flow rate (veh/h)
v_{lr}	median lane demand flow rate (pc/h) (for use in estimating the adjusted median lane flow rate)
v_{lr}	adjusted median lane demand flow rate (veh/h)
v_{lr}	merge flow rate (veh/h/ln)
VMT_i	vehicle miles traveled in segment i (veh-mi)
VMT_{all}	total vehicle miles traveled by all vehicles in directional segment during the 1-hour analysis period (veh-mi)
v_{lr}	flow rate for the outside lane (veh/h/ln)
$v_{lr,w}$	nonweaving demand flow rate in the weaving segment (pc/h)
v_{lr}	opposing demand flow rate (veh/h)
$v_{lr,sh}$	demand flow rate for ATS determination in the opposing direction (pc/h)
$v_{lr,LOS}$	demand flow rate in the opposing direction for calculation of PTSF (pc/h)

AR0074084

v_{ao}	average per-vehicle demand flow rate on all lanes in the ramp influence area (pc/h) including flow in Lanes 1 and 2 (pc/h/ln)
$V_{c,p,t}$	15 min crossing count for ramp pedestrians and bicycles, location t (ped/h)
$v_{d,i}$	directional demand flow rate in the outside lane (veh/h)
$V_{d,p,t}$	15 min entering count for base period and entering location t (ped/h)
v_{ff}	demand flow rate under equivalent base conditions (pc/h/ln, Chapter 11); pedestrian flow per unit width (p/ft/min, Chapter 17)
v_{fo}	pedestrian flow rate (p/min/ft)
$v_{fo,i}$	pedestrian flow rate in the subject direction for base (ideal) hour (p/h)
$v_{fo,m}$	pedestrian flow rate during the pedestrian-service time (p/h)
v_{fo}	flow rate on the on-ramp or off-ramp (pc/h, Chapter 13); maximum value (veh/h, Chapter 14)
HV	volume ratio
$v_i = v_R$	ramp flow that leads the subject quarter, divided by the respective number of lanes
v_{12}	sum of the flow rates in Lanes 1 and 2 and the ramp flow rate for ramps only (pc/h)
$v_{av,y}$	upstream ramp-to-freeway flow (veh)
v_{ff}	ramp to freeway demand flow rate in the weaving segment (pc/h)
v_{fr}	freeway to ramp demand flow rate in the weaving segment (pc/h)
v_{fr}	right-turn demand flow rate (veh/h)
$v_{fr,m}$	right-turn maximum flow rate (veh/h)
v_{fr}	transit frequency for the segment (veh/h)
$v_{fr,m}$	flow rate for the two lanes (veh/h)
v_{fr}	demand flow rate in shared left-turn and through lane group (veh/h)
$v_{fr,s}$	left turn flow rate in shared lane group (veh/h/ln)
v_{fr}	demand flow rate in shared right-turn and through lane group (veh/h)
$v_{fr,s}$	right turn flow rate in shared lane group (veh/h/ln)
v_{fr}	demand flow rate in exclusive through lane group (veh/h/ln, Chapter 17); transit vehicle flow rate in pattern w (v, veh/h, Chapter 12)
v_{fr}	through demand flow rate (veh/h)
v_{fr}	total number of vehicles arriving during analysis period (veh)
v_{fr}	flow rate on the adjacent upstream roadway (pc/h)
v_{fr}	weaving demand flow rate in the weaving segment (pc/h)
v_{fr}	flow rate for one lane (veh/h)
v_{fr}	flow rate of the p movement in the subject shared lane (veh/h)
w	lane width of the lane that the corner movement is negotiating ratio (ft)
W	weaving adjacently factor (1 for W_{fr} = 6 ft); clear width of crosswalk (ft, Chapter 30)
W_{fr}	effective width of combined bicycle lane and shoulder (ft)
W	effective width of sidewalk A (ft)
W_{fr}	available sidewalk width (ft)
W_{fr}	adjusted available sidewalk width (ft)
W_{fr}	pedestrian walk setting (s)
W_{fr}	effective width of sidewalk B (ft)
W_{fr}	width of the bicycle lane (ft)
W_{fr}	buffer width between roadway and available sidewalk (ft)

AR0074085

W_{cs}	curb-to-curb width of face-of-bus stop (ft)
W_e	effective width of crosswalk (ft)
W_i	average effective width of the outside through lane (ft)
W_{ov}	effective overlap width (ft)
W_s	width of signalized intersection approach measured along the segment centerline (ft)
W_{ss}	sum of fixed-object objection widths and lateral features shy distances for a given point along the walkway (ft)
W_{ssp}	adjusted fixed-object objection width on the left of sidewalk (ft)
$W_{ssp,s}$	adjusted roadside objection width on outside of sidewalk (ft)
W_t	width of the outside through lane (ft)
$W_{t,1}$	curb-side lane width (ft)
W_{ts}	width of paved outside shoulder (ft)
W_v	queue change rate (veh/h)
W_w	paved shoulder width (ft)
$W_{w,s}$	shy distance on inside of sidewalk (ft)
$W_{w,s}$	shy distance on outside of sidewalk (ft)
W_x	sum of the widths of the outside through lane, bicycle lane, and paved shoulder (ft)
W_z	total walkway width at a given point along the walkway (ft)
W_z	effective width as a function of traffic volume (ft)
x	degree of utilization
X	volume-to-capacity ratio
X_1	volume to capacity ratio in the shared lane
X_A	average volume-to-capacity ratio
X_c	critical intersection volume to capacity ratio
X_i	volume-to-capacity ratio for lane group i
X_m	weighted volume-to-capacity ratio for all upstream and conflicting pedestrian movements loading on the subject movement group
Y	yellow plus all-red change and clearance intervals (s)
Y_c	sum of the critical flow ratios
y_i	critical flow ratio for phase i
Y_{ped}	duration of the phase serving the minor-street through movement (s)
Y_{ped}	yield point for Phase 2 (s)
y_r	volume-to-saturation flow ratio for the concurrent phase when limited by travel time
h	headway of bunched (mobile stream (s/veh)
h^*	equivalent headway of bunched vehicle stream served by the phase (s/veh)
h_i	headway of bunched vehicle stream in lane group i (s/veh)
h_s	saturation headway (s/veh)
h^*	flow rate parameter for the phase (veh/s)
h_{ci}	flow rate parameter for lane group i served in the concurrent phase that is subject to the barrier (veh/s)
h_i	flow rate parameter for lane group i
h_{ij}	flow rate parameter for the exclusive left-turn lane group (veh/s)
h_{ij}	flow rate parameter for the exclusive right-turn lane group (veh/s)
h_{ij}	flow rate parameter for shared left-turn and through lane group (veh/s)

AR0074086

s_0	flow rate parameter for shared right-turn and through lane group (veh/h)
s_t	flow rate parameter for exclusive through lane group (veh/h)
$s_{v/t}$	standard deviation of spot speeds (mi/h)
SV_i	sum of vehicle-to-space counts (veh)
v_i'	number of proportion of free (unblocked) vehicles for the phase
ψ	proportion of free (unblocked) vehicles in lane group i

AR0074087

VOLUME 1 INDEX

The index to Volume 1 lists the text citations of the terms defined in the Glossary (Volume 1, Chapter 9). Volumes 1, 2, and 3 are separately indexed. In the index listings, the first number in each hyphenated pair of numbers indicates the chapter, and the number after the hyphen indicates the page within the chapter.

A

Acceleration lane, 1-11, 6-22, 7-13
Access point, 2-10, 3-11, 7-12, 8-5
Accessibility, 3-18, 9-11
Accuracy, 2-3, 4-32, 5-4, 6-2, 6-3, 6-6, 6-31, 7-1, 7-3, 7-7, 7-8, 7-37, 8-7, 8-13, 8-21, 8-26, 8-27
Active passings, 2-6, 8-12
Active traffic management (ATM), 6-11
Actuated control, 1-12, 5-10, 6-24
Adjustment, 4-20, 7-8, 7-24
Adjustment factor, 7-8
Algorithm, 1-11, 6-5, 6-27, 7-5
All-way STOP-controlled, 1-12, 2-4, 2-6, 3-11, 3-15, 4-3, 4-4, 4-21, 5-11, 6-12, 6-27, 6-30, 6-32, 7-7, 7-9, 8-3, 8-11, 8-28
Alternative mode, 1-3, 1-4, 1-9, 5-4, 6-1, 6-3, 6-4, 6-9, 6-11, 6-14, 6-15, 6-16, 6-17, 6-19, 7-1, 7-2, 7-3, 7-4, 7-12, 7-20, 7-29, 7-30, 7-32, 8-10, 8-15, 8-16, 8-20
Analysis hour, 3-8, 4-3, 4-4, 4-24, 8-2
Analysis period, 2-11, 2-12, 3-5, 3-6, 6-11, 6-11, 6-16, 6-26, 7-11, 7-12, 7-25, 7-28, 7-32, 7-33, 7-34, 7-35, 7-36, 8-2, 8-17
Analytical model, 6-9, 6-14
Approach, 2-11, 2-12, 2-14, 3-15, 4-14, 4-15, 4-16, 4-21, 4-24, 6-7, 6-9, 6-9, 7-7, 7-12, 7-16, 7-19, 7-30, 7-34, 7-35, 7-37, 7-38, 7-39, 8-11, 8-16, 8-20
Area type, 6-31, 6-32
Arrival rate, 4-16, 4-17
Auxiliary lane, 6-20, 7-16
Average running speed, 4-5
Average spot speed, 4-5
Average travel speed, 4-5, 4-6, 5-5, 5-7, 6-11, 6-30, 7-10, 8-11

B

Back of queue, 4-16, 5-5, 7-11
Base conditions, 2-11, 3-3, 3-14, 3-15, 4-18, 4-2
Basic freeway segment, 2-5, 3-16, 6-4, 6-10, 6-32, 7-5, 7-6, 7-10, 7-40
Bicycle facility, 2-6, 3-22, 3-23, 4-33, 8-11, 8-12
Bicycle lane, 2-2, 3-24, 3-25, 3-26, 4-33, 4-34, 4-37, 5-10, 5-13, 7-6, 8-13
Bicycle level of service (LOS), 1-11, 2-12, 2-16, 2-19, 5-10, 5-13, 6-13, 6-14, 8-13, 8-12
Bicycle mode, 2-11, 2-19, 2-16, 3-22, 8-11, 8-6
Bicycle path, 1-13, 2-5, 3-22, 3-23, 7-25, 4-32, 4-34, 7-38, 8-6
Bicycle speed, 3-22, 4-33, 8-6
Bicycle track, 3-24
Body ellipse, 4-24
Bottleneck, 6-19
Brookshown, 2-11, 2-12, 3-2, 3-3, 6-19
Bus lane, 4-36, 4-37, 4-40
Bus mode, 3-22
Bus stop, 2-2, 3-21, 3-25, 3-29, 4-28, 4-35, 4-36, 4-38, 4-39, 4-40, 5-10, 7-38, 8-7, 8-13

C

Calibration, 6-6, 6-31, 6-16, 6-22, 6-23, 6-24, 6-26, 6-31, 7-29, 7-31
Capacity, 1-1, 1-2, 1-3, 2-1, 2-4, 2-5, 3-1, 3-2, 3-3, 3-4, 4-3, 4-12, 4-13, 4-14, 4-15, 4-16, 5-9, 6-1, 6-2, 6-4, 7-8, 7-9, 7-11, 8-1, 8-2, 8-3, 8-4
Change interval, 4-13, 6-10
Circulation interval, 4-24
Clearance lost time, 4-13
Clearance time, 4-13, 4-39
Climbing lane, 3-14
Cloverleaf interchange, 6-12
Complete trip, 7-38
Computer, 6, Engine, 1-5, 1-6, 6-5
Conflict, 3-15, 4-14, 4-29

AR0074089

Congestion, 2-3, 2-7, 2-8, 2-10, 3-4, 3-12, 3-26, 3-29, 6-4, n-1, 6-22, 7-13, 7-17, 7-32, 7-33, 7-34, 7-35, 7-36, 8-3, 8-8, 8-24
Congestion pricing, 2-3, 6-6, 6-11, n-27, 8-4
Control condition, 4-1, 4-17, 4-18, 6-11, 8-2
Control delay, 2-5, 4-15, 4-34, 5-3, 5-15, 7-7, 7-12, 7-21, 7-23, 7-24, 7-25, 7-35, 7-39
Corridor, 2-9, 2-5, 5-11, 6-15, 6-16
Critical density, 4-8
Critical headway, 4-14, 7-5
Critical speed, 4-9
Crossing lane, 4-24
Crosswalk, 3-15, 3-23, 4-25, 5-14, 9-7
Curb extension, 4-27
Cycle, 2-10, 2-11, 4-11, 4-15, 4-16, 4-17, 4-20, 4-33, 4-34, 6-10, 6-22, 7-11, 7-15, 7-37, 8-5
Cycle failure, 2-11
Cycle length, 4-15, 4-17, 4-20

D

Demand value, 1-3, 1-5, 1-6, 1-8, 1-9, 1-10, 2-1, 2-2, 2-3, n-1, n-2, n-3, 6-10, 6-14, 6-23, 6-31, 6-32, 7-1, 7-2, 7-5, 8-13, 8-14, 8-19
Delay, see Control delay; Geometric delay; Incident delay; Incremental delay; Queue delay; Segment delay; Stopped delay; Time-step delay; Travel delay; Traffic signal delay
Deceleration lane, 6-30
Degree of saturation, 7-27
Demand, see Demand volume; Directional flow rate
Demand flow rate, 5-4, 7-10, 7-15, 7-38
Demand volume, 3-3, 4-2, 6-2, 6-10, n-26, 7-7, 7-10, 7-11, 7-13, 7-24, 7-28, 7-29, 8-4
Demand-to-capacity ratio, 2-8, 5-5, 8-11
Density, 1-10, 4-11, 2-6, 2-11, 2-13, 3-3, 3-9, 3-19, 3-22, 4-1, 4-2, 4-5, 4-7, 4-8, 4-9, 4-25, 4-26, 4-27, 4-29, 5-4, 5-10, 5-12, 6-6, 6-20, n-31, 6-32, 7-5, 7-6, 7-11, 7-12, 7-13, 7-15, 7-25, 7-26, 7-29, 7-30, 7-36, 7-38, 7-39, 8-12
Departure headway, 4-10, 4-14
Descriptive model, 1-7, 1-8
Design hour, 3-8, 3-9, 7-2
Design speed, 4-19, 6-11
Deterministic model, 1-22, 6-7, 6-19, 7-5, 7-39, 8-15
Deterministic queue delay, 7-34
Diameter, 3-10, 3-11, n-31, 6-32, 6-33
Directional distribution, 3-10, 3-11, 4-14, 4-14, 4-20
Directional split, 3-20, 4-29
Diverge, 2-4, 2-5, 2-9, n-19, 7-10, 7-26, 7-32, 8-3
Diverge segment, 2-5, 2-6, 7-10, 7-30, 8-3
Downstream, 2-11, 3-12, 3-13, 4-2, 4-6, 4-17, 6-19, 7-11, 7-15, 7-17, 7-33, 7-37, 8-5
Duration of congestion, 2-8
Dwell time, 3-27, 3-28, 4-36, 4-39, 4-40
Dwell time variability, 4-39
Dynamic traffic assignment model, 7-39

E

Effective green time, 4-11
Effective red time, 4-17
Effective walkway width, 4-29, 4-30
Environmental conditions, 2-13, 8-3
Event, 3-7, 3-22, 6-7, 7-38, 8-7
Exclusive bus lane, 5-28
Exclusive turn lane, 4-19
Extent of congestion, 2-8, 4-3

F

Facility, 3-17, 3-18, 3-19, 3-24, 3-25, 3-28, 3-29, 4-39, 4-40, 5-2, 5-12, n-29
Failure rate, 4-31
Fare-side stop, 4-37, 4-40
Flow rate, 2-11, 2-12, 3-3, 3-14, 3-15, 3-22, 4-1, 4-2, 4-3, 4-4, 4-6, 4-7, 4-8, 4-9, 4-10, 4-11, 4-12, 4-13, 4-16, 4-17, 4-18, 4-21, 4-22, 4-25, 4-27, 4-28, 4-33, 4-37, 4-38, 4-39, 4-40, 4-41, 4-42, 4-43, 4-44, 6-7, 7-13, 8-2
Flow ratio, 2-14
Follower density, 7-26
Follow-up headway, 4-14
Free-flow speed, 1-10, 3-2, 3-3, 3-11, 3-12, 3-14, 3-19, 4-15, 4-24, 4-33, 5-11, 6-21, 6-31, 7-4, 7-6, 7-10, 7-12, 7-21, 7-37, 8-4
Freeway auxiliary lane, 2-10, 8-3
Freeway facility, 3-10, 3-5, 7-4, 7-12, 7-26
Freeway facility capacity, 1-10
Freeway junction, 6-25
Freeway weaving segment, 2-5

AR0074090

Exit ramp, 7-2
Exit ramp terminal, 7-2
Exit ramp terminal, 4-24, 4-32

G

Gap, 1-12, 3-23, 4-7, 4-9, 4-10, 4-14, 4-35, 4-37, 5-13, 6-10, 8-7
Gap acceptance, 4-14, 6-10
Generalized service volume table, 1-16, 2-9, 6-1, 6-3, 6-4, 6-31
Geometric condition, 6-18
Geometric delay, 7-24
Green time, 3-15, 3-16, 3-20, 3-29, 4-13, 4-20, 6-10, 8-2, 8-7

H

Heavy-vehicle conversion, 1-6
Headway, 4-2, 4-7, 4-8, 4-10, 4-11, 4-12, 4-14, 4-15, 6-23
Heavy vehicle, 3-3, 3-15, 3-21, 3-22, 3-25, 4-13, 4-35, 6-31, 6-33, 7-7, 7-10, 7-29, 7-37, 8-2, 8-7, 8-12, 8-14
Hindrance, 3-17, 3-22
Hybrid models, 6-6

I

Incident, 2-10, 3-13, 4-15, 4-21, 5-2, 6-11, 6-21, 8-3
Incomplete trip, 7-33, 7-35, 7-36, 8-17
Incremental delay, 6-20
Incident delay, 4-15
Influence area, 2-4, 7-26, 8-3
Initial queue, 6-18, 7-12, 7-34, 7-37
Intelligent transportation system (ITS), 6-18
Intensity of congestion, 2-8
Interchange, 1-8, 2-5, 2-12, 4-9, 5-14, 6-41, 8-5
Interchange ramp terminal, 1-8, 2-5, 2-13, 5-14, 8-5
Interrupted flow, 2-10, 4-2, 7-34, 8-6
Intersection delay, 3-17, 6-12, 7-16, 6-7
Isolated intersection, 1-11

J

Jam density, 1-8, 7-11

K

K-factor, 3-9, 3-10, 3-11

L

Lane 1, 4-11, 4-6
Lane 2, 3-13, 4-9
Lane distribution, 1-11, 3-11, 3-12, 4-26
Lane width, 1-6, 2-3, 2-11, 3-15, 6-31, 7-6, 7-8, 8-14
Lateral clearance, 4-14
Level of service (LOS), 1-1, 1-2, 2-1, 2-2, 2-3, 3-1, 4-1, 4-4, 6-1, 6-2, 6-1, 6-2, 7-1, 7-2, 7-4, 8-1, 8-8
Link, 7-6, 7-26
Link length, 6-22
Loading area, 4-39, 4-40
Local street, 1-14, 2-14, 3-14, 8-18
Lost time, 4-13, 4-12, 4-21, 6-10
LOS, see Level of service

M

Macroscopic model, 6-6, 6-20, 6-29, 8-15
Mainline, 7-13, 4-21
Major street, 4-14, 4-15, 4-20, 5-1, 8-5, 8-20
Managed lanes, 6-17
Median, 3-11, 3-28, 3-29, 3-8, 5-3, 5-14
Meeting, 7-24, 8-6, 8-7, 8-20
Merge, 3-4, 3-5, 3-6, 6-10, 6-19, 7-10, 7-26, 7-30, 8-3
Mesoscopic model, 6-6, 6-18
Microscopic model, 6-6, 6-18, 6-20, 6-22, 6-27
Minimum green, 3-15
Minor movement, 4-15
Minor street, 4-14, 4-15, 4-20, 4-29
Mixed-traffic operation, 3-28, 4-47
Mobility, 2-14, 3-26, 4-29, 4-34, 5-11, 7-21, 8-8
Mode, 1-12, 2-6, 3-9, 3-1, 3-15, 3-17, 3-22, 3-24, 3-26, 3-27, 3-28, 5-3, 5-8, 5-9, 5-12, 5-14, 6-4, 6-19, 6-32, 7-4, 8-1, 8-6, 8-10
Model, see Descriptive model; Deterministic model; Empirical model; Hybrid model; Macroscopic model; Mesoscopic model; Microscopic model; Normative model; Stochastic model
Model application, 6-5, 6-7

THE NATIONAL ACADEMIES

Advisers to the Nation on Science, Engineering, and Medicine

The **National Academy of Sciences** is a private nonprofit, self-perpetuating society of distinguished scholars engaged in scientific and engineering research, dedicated to the furtherance of science and technology and to their use for the general welfare. On the authority of the charter granted to it by the Congress in 1863, the Academy has a mandate that requires it to advise the federal government on scientific and technical matters. Dr. Ralph J. Cicerone is president of the National Academy of Sciences.

The **National Academy of Engineering** was established in 1964, under the charter of the National Academy of Sciences, as a parallel organization of outstanding engineers. It is autonomous in its administration and in the selection of its members, sharing with the National Academy of Sciences the responsibility for advising the federal government. The National Academy of Engineering also sponsors engineering programs aimed at meeting national needs, encourages education and research, and recognizes the superior achievements of engineers. Dr. Charles M. Vest is president of the National Academy of Engineering.

The **Institute of Medicine** was established in 1970 by the National Academy of Sciences to secure the services of eminent members of appropriate professions in the examination of policy matters pertaining to the health of the public. The Institute acts under the responsibility given to the National Academy of Sciences by its congressional charter to be an adviser to the federal government and, on its own initiative, to identify issues of medical care, research, and education. Dr. Harvey V. Fineberg is president of the Institute of Medicine.

The **National Research Council** was organized by the National Academy of Sciences in 1916 to associate the broad community of science and technology with the Academy's purposes of furthering knowledge and advising the federal government. Functioning in accordance with general policies determined by the Academy, the Council has become the principal operating agency of both the National Academy of Sciences and the National Academy of Engineering in providing services to the government, the public, and the scientific and engineering communities. The Council is administered jointly by both the Academies and the Institute of Medicine. Dr. Ralph J. Cicerone and Dr. Charles M. Vest are chair and vice chair, respectively, of the National Research Council.

The **Transportation Research Board** is one of six major divisions of the National Research Council. The mission of the Transportation Research Board is to provide leadership in transportation innovation and progress through research and information exchange, conducted within a setting that is objective, interdisciplinary, and multimodal. The Board's varied activities annually engage about 7,000 engineers, scientists, and other transportation researchers and practitioners from the public and private sectors and academia, all of whom contribute their expertise in the public interest. The program is supported by state transportation departments, federal agencies including the component administrations of the U.S. Department of Transportation, and other organizations and individuals interested in the development of transportation. www.TRB.org

VOLUME 3
INTERRUPTED FLOW

OVERVIEW

Volume 3 of the *Highway Capacity Manual* (HCM) contains eight chapters that present analysis methods for interrupted-flow system elements—that is, roadways and pathways that have fixed causes of periodic delay or interruption to the traffic stream, such as traffic signals and stop signs. This volume addresses the following types of interrupted-flow system elements:

- *Urban street segments and facilities*, which are portions of roadways that have traffic signals, roundabouts, or stop-controlled intersections spaced less than 2 mi apart on average;
- *Interchanges*, consisting of signalized intersections, two-way stop-controlled intersections, all-way stop-controlled intersections, roundabouts, and interchange ramp terminals; and
- *Off-street pedestrian and bicycle facilities* that (a) are used only by nonmotorized modes and (b) are not considered part of an urban street or transit facility.

VOLUME ORGANIZATION

Vol 3 Ch 1 Interrupted Flow
Ch 16 Urban Street Facilities
Ch 17 Urban Street Segments
Ch 18 Signalized Intersections
Ch 19 TWSC Intersections
Ch 20 AWSC Intersections
Ch 21 Roundabouts
Ch 22 Interchange Ramp Terminals
Ch 23 Off-Street Pedestrian and Bicycle Facilities

Urban Street Segments and Facilities

Urban streets typically serve multiple travel modes, in particular the automobile, pedestrian, bicycle, and transit modes. Travelers associated with each of these modes perceive the service provided to them by the urban street in different ways. Any given operational decision that is intended to improve the service provided to one mode using an urban street can have both adverse and beneficial impacts on the service provided to other modes. The challenge for the analyst is to design and operate an urban street in such a way that all relevant travel modes are reasonably accommodated.

For the purpose of analysis, urban streets are separated into individual elements that are physically adjacent and operate as a single entity in serving travelers. A *node* represents the boundary between links and is represented by an intersection or ramp terminal. A *link* represents a length of roadway between two points. A link and its boundary points are referred to as a *segment*. Multiple contiguous segments can be combined into a single *facility*.

Chapter 17, Urban Street Segments, provides an integrated multimodal methodology for evaluating the quality of service provided to road users traveling along an urban street segment. **Chapter 16, Urban Street Facilities**, provides a similar methodology for evaluating extended lengths of urban streets. In both chapters, level of service (LOS) is reported separately for each mode and is not combined into a single overall LOS. This restriction recognizes that trip purpose, length, and expectation for each mode are different and that their

AR0074099

combination does not produce a meaningful result. The integrated multimodal approach allows analysis of urban streets from a "complete streets" perspective.

Intersections

Five chapters in Volume 3 provide analysis methods for the different kinds of intersections that may be encountered along an urban street.

Chapter 18, Signalized Intersections, describes a methodology for evaluating the capacity and quality of service provided to road users traveling through a signalized intersection. The methodology calculates an array of performance measures describing intersection operation for multiple travel modes: automobile, pedestrian, and bicycle. These measures serve as clues for identifying the source of problems and provide insight into the development of effective improvement strategies. The analyst using this methodology is encouraged to consider the full range of measures.

Chapter 19, Two-Way STOP-Controlled Intersections, presents concepts and procedures for analyzing intersections where one street—the *major street*—is uncontrolled, while the other street—the *minor street*—is controlled by stop signs. These intersections typically occur in one of two configurations: three-leg, where the single minor-street approach is controlled by a STOP sign, and four-leg, where both minor-street approaches are controlled by STOP signs. The methodology is applicable to major streets with up to six lanes, three in each direction. Chapter 19 also provides a methodology for estimating pedestrian delay and LOS in the crossing of major streets at two-way STOP-controlled intersections and at unsignalized midblock crossings.

Chapter 20, All-Way STOP-Controlled Intersections, presents concepts and procedures for analyzing these types of intersections. All-way STOP-controlled intersections require every vehicle to stop at the intersection before proceeding. Because each driver must stop, the decision to proceed into the intersection is a function of traffic conditions on the other approaches. If no traffic is present on the other approaches, a driver can proceed immediately after stopping. If there is traffic on one or more of the other approaches, a driver proceeds only after determining that no vehicles are currently in the intersection and that it is the driver's turn to proceed.

Chapter 21, Roundabouts, presents concepts and procedures for analyzing modern roundabouts. Roundabouts are intersections with a generally circular shape, characterized by yield on entry and circulation around a central island (counterclockwise in the United States). The methodology can be used to assess the operational performance of existing or planned one-lane or two-lane roundabouts.

Chapter 22, Interchange Ramp Terminals, addresses interchanges with signalized intersections, interchanges with roundabouts, and the impact and operations of adjacent closely spaced intersections. Interchange ramp terminals provide the connection between various highway facilities (e.g., freeway–arterial, arterial–arterial), and thus their efficient operation is essential. In addition, they need to provide adequate capacity to avoid affecting the connecting facilities. The chapter's methodology can be applied to the operational and planning level

AR0074100

analysis of a broad range of interchange types, including diamond, partial cloverleaf, and single-point urban interchanges.

Off-Street Pedestrian and Bicycle Facilities

Chapter 23, Off-Street Pedestrian and Bicycle Facilities, provides capacity and LOS estimation procedures for the following types of facilities:

- *Walkways*: paved paths, ramps, and plazas that are generally located more than 50 ft from an urban street as well as streets reserved for pedestrian traffic on a full- or part-time basis;
- *Stairways*: staircases that are part of a longer pedestrian facility;
- *Shared-use paths*: paths physically separated from highway traffic for the use of pedestrians, bicyclists, runners, in-line skaters, and other users of nonmotorized modes; and
- *Exclusive off-street bicycle paths*: paths physically separated from highway traffic for the exclusive use of bicycles.

On-street pedestrian and bicycle facilities are addressed in the other Volume 3 chapters, particularly Chapters 16–19.

RELATED CHAPTERS

Volume 1

The chapters in Volume 3 assume that the reader is already familiar with the concepts presented in the Volume 1 chapters, in particular the following:

- *Chapter 2, Applications*—types of HCM analysis, types of roadway system elements, and traffic flow characteristics;
- *Chapter 3, Modal Characteristics*—variations in demand, peak and analysis hours, K- and D-factors, facility types by mode, and interactions between modes;
- *Chapter 4, Traffic Flow and Capacity Concepts*—traffic flow parameters and factors that influence capacity; and
- *Chapter 5, Quality and Level of Service Concepts*—performance measures, service measures, and LOS.

Volume 2

Urban streets with two or more lanes in each direction that have traffic signals spaced 2 mi or more apart on average are treated as multilane highways. Chapter 14 provides analysis methods for two-lane highways. Two-lane roadways passing through moderately developed areas, such as small towns or developed recreational areas, are treated as Class II two-lane highways and can be analyzed with the methods given in Chapter 15.

35. Active Traffic Management
Case Studies
Technical Reference Library

Access Volume 4 at www.HCM2010.org

Volume 4

Seven chapters in Volume 4 (accessible at www.HCM2010.org) provide additional information that supplements the material presented in Volume 3. These chapters are as follows:

- *Chapter 29, Urban Street Facilities: Supplemental*—examples of applying alternative tools to situations not addressed by the Chapter 16 method for urban street facilities;
- *Chapter 30, Urban Street Segments: Supplemental*—methods for adjusting traffic demand to account for capacity constraints and intersection turning movements, analyzing vehicular traffic flow on a segment bounded by signalized intersections, and estimating major-street delay due to midblock turns; a quick-estimation method for evaluating the operation of a coordinated street segment; a description of field measurement techniques; and documentation of the computational engine;
- *Chapter 31, Signalized Intersections: Supplemental*—descriptions of traffic signal controls; additional field measurement techniques; details of procedures for calculating capacity, phase duration, delay, and back-of-queue; a quick estimation method for determining an intersection's critical volume-to-capacity ratio, signal timing, and delay; documentation of the computational engine; and examples of applying alternative tools to situations not addressed by the Chapter 18 method for signalized intersections;
- *Chapter 32, Stop-Controlled Intersections: Supplemental*—methods for determining the potential capacity of two-way stop-controlled intersections; the operation of two-way stop-controlled intersections with pedestrian effects; and the operation of all-way stop-controlled intersections with three-lane approaches; and additional example problems;
- *Chapter 33, Roundabouts: Supplemental*—guidance on lane-use assignment and calibrating the Chapter 21 capacity model;
- *Chapter 34, Interchange Ramp Terminals: Supplemental*—complete solutions to the Chapter 22 example problems, along with additional example problems; and
- *Chapter 35, Active Traffic Management*—descriptions of active traffic management strategies; a discussion of the mechanisms by which they affect demand, capacity, and performance; and general guidance on possible evaluation methods for active traffic management techniques.

The *HCM Applications Guide* in Volume 4 provides three case studies on the analysis of interrupted-flow facilities:

- *Case Study No. 1* illustrates the process of applying HCM techniques to questions relating to the operational and control needs of an intersection located along a roadway in a university town;

AR0074102

- Case Study No. 2 illustrates the process of applying HCM techniques to the analysis of unsignalized intersections, signalized intersections, and urban streets in the context of a traffic impact analysis; and
- Case Study No. 3 illustrates the consideration of nonmotorized modes as part of the evaluation of signalized and unsignalized intersections.

These case studies focus on the process of applying the HCM rather than on the details of performing calculations (which are addressed by the example problems in the Volume 3 and supplemental Volume 4 chapters). The case studies' computational results were developed by using HCM2000 methodologies and therefore may not match the results obtained from applying the HCM 2010. However, the process of application is the focus, not the specific computational results.

The Technical Reference Library in Volume 4 contains copies of (or links to) many of the documents referenced in Volume 3 and its supplemental chapters. The Technical Reference Library also provides computational engines (spreadsheets) to assist with the application of the urban streets, signalized intersections, all-way STOP-controlled intersections, and roundabouts methodologies.
